FRINGI'LLIDÆ, a family of Birds belonging to the order *Insessores* and the division *Conirostres*. This family is commonly known by the name of Finches. According to Mr. Vigors this family embraces, in addition to *Alauda* [ALAUDINÆ], to which *Emberiza* (the Buntings) [EMBERIZIDÆ] and its affinities seem more nearly allied, the greater part of the Linnæan *Fringillæ*, together with the Linnæan *Tanagræ* [TANAGER], which approach them in their external characters and in their habits, as far as has hitherto been ascertained. These latter groups contain many natural genera which may be traced, in his opinion, from the point of their connection with the Linnæan *Fringillæ* back, by a gradual increase of the base of the bill in breadth and height, to the family of *Loxiadæ* [LOXIADÆ], which unites with them at the opposite extremity of the series of families which compose the tribe. The *Fringillidæ* again, according to the same author, by means of the sharp-pointed and lengthened bill of *Carduelis*, and by the extension of the culmen of the upper mandible in an angular form for some extent upon the front of the head, conduct us on the other side to the genus *Icterus* (Briss.), which commences the succeeding family. Here Mr. Vigors thinks that the genus *Ploceus* of Cuvier also seems to hold an intervening station between the two groups, so as to render it difficult to decide in which of them it should be placed. There is also, he states, another decided line of relationship between the two families, namely, that which some species of the Linnæan *Alauda*, particularly *A. Capensis*, bear to the *Sturnus Ludovicianus*, or Crescent Stare, of Dr. Latham. This latter bird is well known as the *Alauda magna* of Linnæus and of the American ornithologists. But its still stronger affinity to the *Sturni* and *Icteri* necessarily places it among them. The former relationship appears to Mr. Vigors to be one of analogy, not of affinity; while the direct passage between the families is found in *Ploceus* (the Weaver Birds). [PLOCEUS.] Mr. Vigors makes *Fringillidæ* the first, and *Loxiadæ* the last family of the *Conirostres*. Mr. Swainson makes the *Fringillidæ* (including *Loxia*, apparently; for his *Conirostres* consist of the *Corvidæ*, *Sturnidæ*, *Fringillidæ*, *Musophagidæ*, and *Buceridæ*, omitting *Loxiadæ*) the third family; and the order of the names given will show the position he assigns to it. "No group in the ornithological circle," writes Mr. Swainson in his 'Classification of Birds,' vol. i., "exhibits this powerful structure (strength of the bill) so much as that of the *Fringillidæ*, where the bill is short and nearly conic; both mandibles are equally thick, and when closed their height and breadth are nearly the same. In many of the Finches (as in the sub-genera *Amadina*, *Coccothraustes*, &c.) the thickness of the bill at its base in comparison to the size of the head is enormous; but in *Loxia ostrina* of Vieillot, a rare and most extraordinary bird from Western Africa, the bill is not much inferior to the size of the head. It is well known that all these 'hard-billed' birds, as the old writers aptly called them, feed entirely upon seeds and nuts; and the harder these are the stronger are the bills of such species as are appointed to derive nourishment from the different sorts; whenever an insectivorous and frugivorous diet is united, as is the case with most of the Tanager Finches, the upper mandible is notched for the obvious purpose of more firmly securing that part of their food which can escape."

M. Lesson, in his 'Table Méthodique,' places the *Fringillidæ* as the third family of the *Conirostres*, and makes it consist of the following genera:—*Emberiza* of Linnæus, Emberizoïdes of Temminck, *Fringilla* of Linnæus—namely, *Pyrgita*, *Fringilla*, and *Carduelis* of Cuvier; *Linaria* of Bechstein; *Vidua* of Cuvier; *Coccothraustes* of Brisson; *Pyrrhula* of Brisson; *Loxia* of Brisson; *Psittirostra* of Temminck; *Corythus* of Cuvier; *Colius* of Brisson and Linnæus; *Phytotoma* of Molina; and *Ploceus* of Cuvier.

Cuvier, in his 'Règne Animal,' arranges the Buntings (*Emberiza* of Linnæus) immediately after the Titmice (*Parus* of Linnæus); and next to the Buntings he places the Sparrows, Les Moineaux (*Fringilla* of Linnæus).

Cuvier designates the Buntings as possessing an extremely distinct character in their conical short straight bill, the narrower upper mandible of which, entering within the lower, has on the palate a hard and projecting tubercle; and as granivorous birds which have little caution, and readily enter the snares prepared for them. Those Buntings which have an elongated nail on the hind toe, like the larks, are distinguished by Meyer under the generic name of *Plectrophanes*.

The Sparrows (*Fringilla*) are characterised by Cuvier as having a conical bill more or less large at its base, but not angular at the commissure. They subsist principally on seeds, and are subdivided by that zoologist as follows:—The Weavers (*Ploceus*, Cuvier), a form found in both the old and the new continents. Those of the Old World make a nest by interweaving very skilfully the fibres of vegetables, whence their name. Such are the Toucnam Courvi of the Philippine Islands (*Loxia Philippina* of Linnæus), with its pendulous nest, having a vertical canal opening below, which communicates laterally with the cavity where the young are laid; and the Republican (*Loxia socia* of Latham), which builds in society, and whose conjoined nests form one large continuous mass with numerous compartments. Among the Weavers of the new continent Cuvier places Le Mangeur de Riz, Petit Choucas de Surinam, de la Jamaique, Cassique Noir, &c. (*Oriolus niger*, *Oriolus oryzivorus*, *Corvus Surinamensis*, Gmelin), which in countless flocks lay waste the fields of many of the warm parts of America. Next to the Weavers are placed the Sparrows, properly so called (*Pyrgita* of Cuvier), of which the well-known Common or House-Sparrow (*Fringilla domestica* of authors, *Pyrgita domestica* of Cuvier), the companion of civilised man on a large portion of the globe, may serve as the type. Cuvier makes the Finches, Les Pinçons (*Fringilla* of Cuvier), follow. These have the bill rather less arched than the sparrows, and a little longer and stronger than the linnets. Their habits are more gay and their song more varied than those of the sparrows; and the Chaffinch, Le Pinçon Ordinaire (*Fringilla cœlebs* of Linnæus), may be taken as an illustration of the genus. [CHAFFINCH.] The Linnets and Goldfinches (Les Linottes, *Linaria* of Bechstein), and Chardonnerets (*Carduelis* of Cuvier) come next, and the Serins or Tarins, Canary Birds, for example. [CANARY BIRD.] Then come the Whidah Finches, Widow-Birds, as they are popularly called (*Vidua* of Brisson and other authors); and next to them the Grosbeaks, Gros-Becs (*Coccothraustes* of Brisson and others), to which Cuvier considers there is a gradual passage from the linnets without any assignable interval, and whose completely conical bill is only distinguishable by its excessive size: of these the Common Grosbeak (*Loxia Coccothraustes* of Linnæus) may be considered as the type. *Pitylus*, to which Cuvier assigns certain foreign species, succeeds. It has, as well as *Coccothraustes*, a large bill, which is slightly compressed, arched above, and sometimes has a salient angle in the middle of the edge of the upper mandible. The Bullfinches (*Pyrrhula*) conclude the tribe.

After the Sparrows Cuvier places the Crossbills (*Loxia* of Brisson), and the Durbecs (*Corythus* of Cuvier, *Strobilophaga* of Vieillot), observing that they cannot be placed at a distance from the bullfinches and crossbills. The bill of *Corythus*, convex all round, has its point curved above the lower mandible. *Colius* he considers as nearly approaching the preceding.

M. Temminck thus defines the character of the Buntings (*Emberiza* of Linnæus):—Bill short, strong, conical, compressed, trenchant, without a notch; mandibles having their edges included (the upper mandible being smaller than the lower), and a little distant from each other at the base. Nostrils basal, rounded, surmounted by the frontal feathers which partially cover them. Feet with three anterior and one posterior toe, the anterior toes entirely divided and the posterior toe with a short and curved nail: in a small number of species this nail is straight and long. Wings with the first quill rather shorter than the second and third, which are the longest. Tail forked or slightly rounded.

It will be observed that in this generic character M. Temminck has omitted the projecting tubercle on the palate, and he gives as a reason for this omission that it is not visible externally.

The principal food of the Buntings consists of farinaceous seeds, to which insects are occasionally added. The greater number haunt woods and gardens, and build their nests in bushes. Those which have the posterior nail or claw long live among the rocks, or in the plains, and do not frequent the woods. In almost all the species the sexes present a marked difference, the males being variegated with lively and well-defined colours. The young may be distinguished from the females, which they much resemble, by their more sombre colouring, and a greater number of deep spots. None of the indigenous species moult twice, but the greater part of the foreign species do so regularly, and the colours of the males change considerably in these two moults: in the summer they are adorned with brilliant colours; in the winter they put on the modest livery of the females. (Temminck.)

The same ornithologist divides the Buntings into two sections:—

I. The Buntings properly so called.

These have the posterior claw short and curved, and live in the woods and gardens. They appear to moult but once a year. Some parts of their plumage, which are coloured with lively tints in the summer, are clouded in winter by the ashy shading with which the feathers are terminated; these colours are without mixture in the spring, especially the deep black, till it becomes clouded with reddish after the autumnal moult. The common Yellow Hammer (*Emberiza citrinella*) may be taken as an example of this section, which also contains, among other species, the Ortolan (*Emberiza hortulana* of Linnæus, Ortolan Bunting of Latham) and the Cirl-Bunting (*Emberiza Cirlus* of Linnæus).

II. The Spur-Buntings (Bruans Eperonniers, Plectrophanes of Meyer).

This section has the back claw long and but very slightly arched. The species composing it live always on the ground in open places. Their moult is simple and ordinary, but the colours of the plumage change considerably by rubbing and the action of the air and light, so that their summer dress appears very different from that which these birds assume in the autumn.

The numerous genera into which, as we have seen, the genus *Fringilla* of Illiger has been subdivided, do not accord with M. Temminck's views; and as this excellent ornithologist has as much practical experience as any of those who have made this interesting branch of natural history their study, and perhaps more, we think it right to put the student in possession of his opinions on this subject.

M. Temminck, then, thus defines his genus Gros-Bec (*Fringilla* of Illiger):—Bill short, strong, convex, straight, and completely conical; upper mandible swollen as it were, a little inclined towards the point, without any arête, and with the upper part depressed, often prolonged into an angle between the frontal feathers. Nostrils basal, round, placed near the front, behind the horny elevation of the swollen part of the bill, partially hidden by the feathers of the front. Feet with the tarsus shorter than the middle toe; the anterior toes entirely divided. Wings short; the second or third quills graduated, the third or fourth longest. Tail varying in form.

These birds, according to M. Temminck, feed on all sorts of seeds and grains, which they open with the bill, at the same time rejecting the husk; it is only very rarely that insects are added to this diet. They inhabit all the countries of the globe, but particularly the regions of the torrid zone and warm latitudes. They raise many broods annually, collect together in numerous flocks, and migrate in associated flights. Of all the winged class they are, after the Pigeons and Gallinaceous Birds, the most easily domesticated. The greater number of foreign species and some European undergo a double moult. When this takes place, the male assumes in winter the livery of the female. The young of the year differ from the old ones before the autumnal moult; but after that period it becomes impossible to distinguish them.

Upon this extensive genus M. Temminck proceeds to remark that methodists have essayed to class these birds in many genera, under the designations of *Strobilophaga*, *Coccothraustes*, *Fringilla*, *Passer*, *Pyrgita*, *Vidua*, *Linaria*, and *Carduelis*. The manners of all these birds being, with some slight shades of difference, absolutely the same, it is impossible, in his opinion, to have recourse to the invention of new names as the means of subdividing this great group. M. Temminck declares that he took the greatest pains to compare more than a hundred foreign species with our indigenous species, and the result of this examination confirmed him in the conclusion that there exists a gradual passage, without any demarcation, from one species to another. This natural series has, he observes, been recognised by Illiger, who unites all these birds with a thick and conical bill ('à bec gros et conique') in one great genus under the name of *Fringilla*, comprising the Bullfinches (*Pyrrhula*) therein. M. Temminck, however, thinks that these last ought to be classed in a distinct genus, in consequence of the form of the bill, certain habits, and perhaps also with reference to the countries they inhabit. The genus *Loxia*, he remarks, has been restored by Illiger to the limits assigned to it by Brisson; and he adds that he (M. Temminck) has separated from the genus *Loxia* of Linnæus a species singularly characterised by the form of the bill, under the name of *Psittirostra*. M. Cuvier, he goes on to observe, has, in the 'Règne Animal,' indicated, rather than established characteristically, many genera and sub-genera. M. Cuvier allows that there is a gradual passage, without any assignable interval, from the Linnets to the Grosbeaks. The species of his genus *Vidua*, or Widow-Birds, are distinguished by some of the upper coverts of the tail being excessively elongated in the males. This distinction, available for recognising the males only, disappears in the moult; for in winter they have no conformation of the tail differing from that of the females; and at that season it would be difficult to pronounce whether they were Linnets, Sparrows, or Finches (Pinsons). M. Temminck agrees that to facilitate the methodical arrangement of the great number of species composing this genus, it is necessary to have recourse to an artificial classification, by the aid of which the species may be easily found. The simplest method, in his opinion, is to form three sections in the genus *Fringilla*, under indications which have more or less reference to the three different groups of bills, which may be separated into *Laticones*, *Brevicones*, and *Longicones*. In the first section may be comprised, he thinks, the greater number of the pretended *Loxiæ* of authors, some soi-disant Bengalies, and the Sparrows (Moineaux), which resemble ours in the colours of their plumage; in the second, some Sparrows (Moineaux) of authors, the Finches (Pinsons), the Linnets (Linottes), and those indicated as Widow-Birds (*Viduæ*), Bengalies, and Senegalies; in the third the Tarins, some Senegalies, and the Chardonnerets.

I. *Laticones.*

Bill large, convex, more or less swollen on the sides.

The Grosbeak, Haw-Grosbeak, or Hawfinch (*Loxia Coccothraustes* of Linnæus, *Fringilla Coccothraustes* of Temminck), is placed by that author at the head of this section, which contains, among other species, the Green Grosbeak or Greenfinch (*Loxia chloris* of Linnæus, *Fringilla chloris* of Temminck) and the Common Sparrow.

II. *Brevicones.*

Bill in the shape of a cone, more or less short, straight, and cylindrical, often conical throughout.

M. Temminck commences this section with the Chaffinch. The Linnets also belong to it.

III. *Longicones.*

Bill in the form of a straight cone, long, and compressed; points of the two mandibles sharp.

The Citril Finch (*Fringilla Citrinella* of Linnæus) appears at the head of this section, which also comprises, among other species, the

Siskin (*Fringilla spinus* of Linnæus), the Lesser Redpole, and the Goldfinch.

In the second volume of his 'Classification of Birds,' Mr. Swainson makes the *Coccothraustinæ* the typical group, a sub-family composed of the Hawfinches, Weavers, Goldfinches, and Linnets. They live entirely upon trees, and have the bill very strong and entire. Genus, *Coccothraustes;* sub-genera, *Pyrenestes* (Sw.), *Coccoborus* (Sw.), *Coccothraustes* (Briss.), *Spermophaga* (Sw.), *Dertroides* (Sw.). Genus, *Ploceus;* sub-genera, *Vidua* (Cuv.), *Euplectes* (Sw.), *Ploceus* (Cuv.), *Symplectes* (Sw.). Genus, *Amadina* (Sw.) (Bengaly); sub-genera, *Estrelda* (Sw.), *Amadina* (Sw.), *Spermestes* (Sw.), *Erythura* (Sw.), *Pytelia* (Sw.). Genus, *Tiaris* (Sw.); Genus, *Carduelis* (Sw.); Genus, *Linaria* (Briss.); sub-genera, *Linaria*, *Leucosticte* (Sw.), *Chloris* (Sw.). The second or sub-typical group he makes to contain the *Tanagrinæ*. Genus, *Tardivola* (Sw.); Genus, *Tanagra* (Linn.); sub-genera, *Pitylus* (Cuv.), *Tanagra* (Linn.), *Ramphopis* (Vieill.). Genus, *Phœnisoma* (Sw.); sub-genera, *Lamprotes* (Sw.), *Phœnisoma* (Sw.), *Tachyphonus* (Vieill.), *Leucopygia* (Sw.). Genus, *Nemosia* (Vieill.); Genus, *Aglaïa* (Sw.); sub-genera, *Euphonia* (Sw.), *Tanagrella* (Sw.). Genus, *Pipillo* (Vieill.); sub-genera, *Arremon* (Vieill.). The third consists of the *Fringillinæ*, or True Finches, differing materially from the two former; their bills are generally smaller, but more perfectly conic; seeds form their food almost entirely; and they chiefly live upon the ground. Genus, *Pyrgita* (Antiq.); sub-genera, *Aimophila* (Sw.), *Leucophrys* (Sw.). Genus, *Fringilla* (Linn.); sub-genera, *Passerella* (Sw.), *Fringilla*, *Zonotrichia* (Sw.), *Ammodramus* (Sw.), *Chondestes* (Sw.). Genus, *Emberiza;* sub-genera, *Emberiza* (Linn.), *Fringillaria* (Sw.). Genus, *Leptonyx* (Sw.); sub-genus, *Melophus* (Sw.). Genus, *Plectophranes* (Meyer); sub-genera, *Miliaria* (Sw.), *Plectrophanes* (Meyer). Genus, *Agrophilus* (Sw.). The fourth contains the *Alaudinæ*. Bill much more slender than in any of the preceding; hind claw always more or less lengthened. Genus, *Alauda* (Linn.); Genus, *Calendula* (Linn.); sub-genera, *Myafra* (Horsf.), *Braconyx* (Brachonyx ?) (Sw.). Genus, *Agrodroma* (Sw.); Genus, *Macronyx* (Sw.); Genus, *Certhilauda* (Sw.). Mr. Swainson considers that the *Alaudinæ* pass into the fifth, the *Pyrrhulinæ* (Bullfinches). Genus, *Pyrrhulauda* (Smith); Genus, *Pyrrhula;* sub-genera, *Crithagra* (Sw.), *Spermophila* (Sw.). Genus, *Psittirostra* (Temm.); Genus, *Corythus* (Cuv.); Genus, *Hæmorrhous* (Sw.).; Genus, *Loxia* (Linn.).

In Mr. Darwin's collection is a series of Ground-Finches, so peculiar in form that Mr. Gould was induced to regard them as constituting an entirely new group, containing fourteen species, and appearing to be strictly confined to the Gallapagos Islands. He proposes the following generic names for them: *Geospiza*, *Camarhynchus*, *Cactornis*, and *Certhiada*. Mr. Darwin remarks that these birds are exclusively confined to the Gallapagos Islands; but their general resemblance and their indiscriminate association in large flocks rendered it almost impossible to study the habits of particular species. In common with nearly all the birds of these islands, they are so tame that the use of the fowling-piece in procuring specimens was quite unnecessary. They appeared to subsist on seeds deposited on the ground in great abundance by a rich annual crop of herbage. ('Zool. Proc.,' 1837.)

Having thus endeavoured to give the student a general sketch of this family of birds, and the views of some of the leading ornithologists with regard to them, we conclude with a list of the species found in the British Islands as given in Mr. Yarrell's work on 'British Birds.'

Passer montanus, the Tree-Sparrow; *Fringilla montana*, Penn.; *Pyrgita*, Fleming; *Passer montanus*, Selby; *Fringilla montana*, Jenyns; *Pyrgita*, Gould; *Fringilla*, Temm. [PASSER.]

Passer domesticus, the House-Sparrow; *Fringilla domestica*, Penn.; *Pyrgita*, Fleming; *Passer domesticus*, Selby; *Pyrgita*, Gould. [PASSER.]

Coccothraustes chloris, the Green-Finch or Grosbeak; *Loxia chloris*, Penn.; *Coccothraustes*, Fleming; *Fringilla*, Jenyns. [COCCOTHRAUSTES.]

Coccothraustes vulgaris, the Haw-Finch; *Loxia Coccothraustes*, Penn.; *Fringilla Coccothraustes*, Jenyns; *Caccothraustes vulgaris*, Gould; [COCCOTHRAUSTES.]

Carduelis elegans, the Goldfinch; *Fringilla Carduelis*, the Goldfinch; *Carduelis elegans*, Selby and Gould. [CARDUELIS.]

Carduelis spinus, the Siskin; *Fringilla spinus*, Penn.; *Carduelis*, Selby and Gould; *Fringilla*, Jenyns and Temm. [CARDUELIS.]

Linota cannabina, the Common Linnet; *Fringilla Linota*, Linnet-Finch of Penn.; *F. cannabina* Red-Headed Finch; *F. Linota*, Brown Linnet; *F. cannabina*, Greater Redpolo; *F. Linota*, the Linnet of Bewick; *Linaria*, of Selby; *Fringilla*, Gros-Bec Linote of Temm. [LINOTA.]

Linota canescens, the Mealy Redpole of Gould and Bonaparte; *L. borealis*, Macgillivray; *Fringilla*, Gros-Bec Boreal, Temm. [LINOTA.]

Linota linaria, the Lesser Redpole, or Common Redpole; *Fringilla linaria*, Lesser Red-Headed Finch of Pennant; Rose-Linnet of Fleming; *Linaria minor*, Lesser Redpolo Linnet of Selby and Gould; Gros-Bec Sizerin of Temminck. [LINOTA.]

Linota montium, the Mountain Linnet, or Twite; *Fringilla montana*, Twite-Finch of Penn. and Gould; *F. montium* of Montague and Jenyns; Mountain Linnet of Bewick. [LINOTA.]

Pyrrhula vulgaris, the Bulfinch. It is *Loxia pyrrhula* of Pennant, Montague, and Bewick; *Pyrrhula vulgaris* of Fleming, Selby, Jenyns, and Gould. [BULLFINCH.]

Pyrrhula enucleator, the Pine Grosbeak; *Loxia enucleator* of Penn.; *Corythus*, Common Hawfinch of Fleming and Gould; *Pyrrhula*, Pine Bulfinch of Selby and Jenyns.

FRITILLA'RIA, a genus of Plants belonging to the natural order *Liliaceæ*. It has a perianth of 6 leaves with a nectariferous depression at the base of each; the style trifid at the apex; the seeds flat. Of this genus the Common Fritillary, *F. meleagris*, is a native of Great Britain. It has a single-flowered leafy stem, the leaves all alternate and linear-lanceolate. It inhabits meadows and pastures, and is found throughout Europe. It has flesh-coloured flowers, with numerous dark and sometimes white spots. *F. montana*, grows in the mountainous districts of Europe. It has the 2 floral leaves, opposite, and distinct from those of the stem. *F. pyrenaica* of Sibthorp, the *F. tulipifolia* of Bieberstein, is found in Greece. The species are often cultivated in gardens on account of their flowers. They blossom in April and May, and will grow in any common garden soil. (Babington, *Manual of British Botany;* Koch, *Flora Germanica.*)

FROG. [AMPHIBIA.]

FROGSBIT. [HYDROCHARIS.]

FROND, a botanical term intended to express such organs as are composed of a stem and a leaf combined. The leaves of ferns and palms were thought to be of this nature. It is not now however applied to the leaves of palms, but is still employed to express those leaf-like expansions of the *Cryptogamia* which bear the organs of reproduction.

FRONDICULARIA. [FORAMINIFERA.]

FRONDIPORA. [MILLEPORIDÆ.]

FRUIT. In botanical language, that part of the plant which in the early stages of its growth is called the Pistil [PISTIL], and which contains the ovules or seed-buds, becomes the Fruit, when the ovules by the presence of the embryo, are changed into seeds. The Style and Stigma, when they still remain, retain their names, but the Germen is called the Pericarp. In this sense, there are of course some plants which have no Fruit, because they are not provided with a Germen; these therefore have naked Seed-Buds, or Ovules, and also naked Seeds (Semina nuda); such are *Coniferæ*, *Cycadaceæ*, and *Loranthaceæ*. But there are some plants in which the germen is easily destroyed, so that the seed-bud is developed without an envelope to the seed: these, in order to distinguish them from the former, are termed Semina denudata, as in *Leontice* and *Peliosanthes*.

Fruits may be divided, according to the analogy of the flower, into Naked and Covered (Fructus nudus et Fructus tectus), according as the germen only appears to exist, as in *Lilium*, or as this is surrounded by other floral parts, as in *Nicandra*. When one pistil is developed into a fruit it is called a simple fruit (fructus simplex), as in *Nigella;* when several, a compound or multiple fruit (fructus multiplex), as in *Ranunculus*.

The parts of the Fruit are the Pericarp, the Spermophore, the Funiculus, and the Pulp.

The Pericarp is the transformed germen: sometimes it is united with the other persistent parts of the pistil, style, and stigma. The latter are seldom of particular importance; and all that need be said of them is that they are sometimes retained, as in *Papaver*, or they are more developed, as in *Pulsatilla*. The forms of the pericarp are exceedingly diversified, but admit of no general definition: they frequently exhibit hairs, prickles, protuberances, and membranous expansions (alæ), prominent ribs (costæ or juga), and pits in their interspaces (valleculæ), &c. The pericarp essentially determines the varied appearances of the fruit, by its diversity of structure. The parenchyma of the germen is developed in various ways. In the simplest cases, we find in the mature pericarp only the epidermis of both surfaces, and between these a uniform layer of parenchyma, without vascular bundles, as in the lower *Araceæ*, or traversed by a few simple bundles. In other cases only the epidermis of the external surface is perceptible, whilst the entire parenchyma, with the epidermis of the inner surface, is succulent or fleshy, as in *Atropa;* or it may be, that under the epidermis of the outer surface some layers of cellular tissue are woody, whilst the underlying are fleshy; in both cases very frequently passing without determined boundary into the pulp.

In many other cases four layers are distinctly discernible, and have been named, counting from without inward, Epicarp, Mesocarp, (also Sarcocarp, or Flesh, 'caro'); and the two inner undistinguished coats, the Endocarp. Those varieties of structure in the fruit are most important which cause the peculiar solutions of the continuity in the fully mature condition. Hence we obtain two comprehensive classes of fruits, according as their construction causes a separation into individual parts or not. The latter may be termed the berry-like, and the former the capsular. The capsular are again divided into two groups, according as the pericarp either opens and suffers the seed to escape—Capsules with their portions called valves; or separates into individual parts, which do not again open, but firmly inclose the seed—Splitting Fruits (Schizocarps), and their parts called Mericarps. The Berry-like Fruits are also sub-divided into three groups, according as the inner layers are the more tough and solid, and the outer the more fleshy and juicy—Stone Berries (Drupes); or the reverse—True Berries (Baccæ); or, lastly, all the layers appear thin and dry, or leathery (Achænia). All these forms may, with the germen from which they arise, be superior or inferior, one- or many-celled, or one- or many-seeded: which only require to be noticed when deviations in the structure of the germen have arisen through abortion, being otherwise self evident.

a. The Capsular Fruits occur in the most diverse families. The mode of bursting (Dehiscence) is especially to be observed. The simplest process is an apparent wholly irregular tearing open at any place, as in *Nicandra*: usually however the form of this dehiscence is very regular, even though it may be confined to a small part of the fruit, as in *Papaver*, *Antirrhinum*, &c.

The solution of continuity is either vertical or horizontal: in the latter case, the upper part forms a kind of cover upon the under, and the capsule is termed circumscissile. In the first case, the pericarp, &c. falls away in more or fewer separate pieces, which are termed valves. In many-celled fruits the valves may separate entirely from the persistent septa, as in *Cobœa scandens* (dehiscentia septifraga); or the septa may split into two lamellæ, and each valve may bear one of these lamellæ on each of its margins (dehiscentia septicida, valvulæ margine septiferæ); or the septa may remain undivided, adherent to the middle of the valves (dehiscentia loculicida, valvulæ medio septiferæ). If in any of these kinds of dehiscence a stalk-like mass of cellular tissue remains standing in the axis of the fruit, it is called the Columella.

From what has been said, it is sufficiently evident that these solutions in the continuity are not at all dependent upon the original composition. Such a relation has been assumed; and to the line in the external circumference of the pericarp, where the edges of real or pretended carpels have become blended, the term 'dorsal suture,' has been applied, while the term 'ventral suture' designates merely the line where the margins of one and the same carpel or similar part have become blended.

In the generality of capsular fruits, the above-mentioned four layers of the pericarp may be distinguished from each other; but they are usually very thin and membranous or leathery, or more rarely woody.

b. The Schizocarps, or Splitting Fruits, are usually distinguished chiefly according to the direction in which the cleft occurs. This is either parallel with the axis of the fruit, or perpendicular to it, that is, the solution of continuity is either vertical or transverse. In both, the separate parts are usually only one-seeded. In the first case the separate parts are sometimes named Cocci or Mericarps, in the last case Joints or Articulations; and they are distinguished, according to the texture of their layers, as dry, coriaceous, and succulent. The first (the mericarps) are proper to the families *Rubiaceæ*, *Euphorbiaceæ*, *Labiatæ*, *Boraginaceæ*, *Geraniaceæ*, *Tropæolaceæ*, *Malvaceæ*, *Umbelliferæ*, &c., &c.; the last (the joints) to some of the *Leguminosæ* and *Cruciferæ*. In the first a columella is not uncommon.

c. The Stone-Berries, characteristic of the *Amygdaleæ*, but also presented in other families, owe their peculiarity to the remarkable diversity in the structure of their layers, and indeed of the parenchyma layers, the inner of which are always hard, and often woody; whilst the outer are fleshy or coriaceous: both are developed in a greater thickness than usual.

d. The True Berries, predominating in the families of *Grossulariaceæ*, *Passifloraceæ*, *Cucurbitaceæ*, and the *Araceæ*, and occurring occasionally in many other families, depend essentially on the fleshy or juicy texture of the inner layers of the pericarp: this condition often exists to the extent of a dissolution into single cells, tumid with fluid, whilst the external layers are solid, and sometimes even woody, as in *Lagenaria*.

e. The Achænia, with always thin dry layers, not usually distinguishable, characterise the families of the Grasses, *Cyperaceæ*, *Cupuliferæ*, *Compositæ*, and *Dipsaceæ*, predominate in the *Dryaceæ* and *Ranunculaceæ*, and occur singly in other cases. They are one-celled and one-seeded, generally originally, but sometimes, as in the *Cupuliferæ*, through abortion of cells and seed-buds.

With regard to the Spermophore it may be remarked, that in the dehiscence of the fruit portions of cellular tissue are separated from the valves or septa, to which the seeds remain suspended, and which have been termed Spermophores. In these separations sometimes actually independent organs become solved from their union with others, as in *Cruciferæ*, and sometimes merely pieces of independent organs become detached, as in the *Asclepiadaceæ*.

The Pulp in the fruit assumes two conditions; on the one hand it passes into the loose cellular tissue of the pericarp in the true berries, as in *Solanum*; and on the other into the subsequent products of the funiculus; namely, into the aril in its widest sense, as in *Arum*, and probably into the true aril, as in *Ribes*.

The Funiculus exhibits manifold varieties, such as hairs, warty expansions among the seeds, membranous, continuous, or lobed envelopes of the seed (arils), and so forth.

There are often parts external to the germen, which are persistent till after the maturation of the seed [SEED], and they often undergo many changes; and when they become fleshy they assume the appearance of fruits. They are called Spurious Fruits. The most remarkable example of this is seen in the case of the fruit of the Fig (*Ficus*), in which the peduncle or receptacle swells up and incloses the true fruits. The pedicel in *Hovenia dulcis* also swells up and assumes the form of a fruit. In the Pine-Apples (*Ananassa*) the bracts enlarge and become the part eaten. In the Mulberry (*Morus*) the perianth is the fleshy part; in the Bladder-Campion (*Cucubalus baccifer*) the calyx enlarges; in *Mirabilis* it is the corolla; and the hips of the Rose (*Rosa*) are the dilated disc, whilst in the Strawberry (*Fragaria*) the sweet juicy part is the receptacle.

The terms applied to the fruits of plants by botanists are very numerous. The same kind of fruit has frequently several names, whilst the same name has been applied to several different kinds of fruits. The following enumeration of some of these terms is given by Schleiden in his 'Principles of Scientific Botany,' whose remarks on this subject deserve careful attention from those interested in the further development of this subject:—

Enumeration of the Various Forms of Fruit.

I. Seed naked (*Semen nudum*).
- *A.* Seed solitary.
  - 1. *Bacca.* Seed inferior. Ex. *Viscum.*
  - 2. *Sphalerocarpium.* Seed with a fleshy aril. Ex. *Taxus.*
- *B.* Fructifications.
  - 3. *Strobilus.* Spikes with woody spermophores. Ex. *Pinus.*
  - 4. *Galbulus.* Capitula with confluent fleshy bracts. Ex. *Juniperus.*

II. Simple Fruits (*Fructus simplex*).
- *A.* Capsule (*Capsula*).
  - † Superior.
  - 5. *Capsula circumscissa.*
  - 6. *Utriculus*, Gärtner, No. 5. One-celled, originating from a carpel; few-seeded. Ex. *Chenopodium.*
  - 7. *Pyxidium*, No. 5. One- or many-celled, formed of several carpels; many-seeded. Ex. *Hyoscyamus.*
  - 8. *Folliculus.* One-celled, or many-celled, one-valved. Seeds on the two margins of the valve. Ex. *Pæonia.*
  - 9. *Conceptacula.* Two disunited *folliculi* with one separating spermophore. Ex. *Asclepias.*
  - 10. *Legumen.* One-celled, 1-seeded, or many-seeded, two-valved. Seeds on the two borders of one fissure. Ex. *Pisum.*
  - 11. *Siliqua.* Two-celled, two-valved, separating from the persistent spermophore, forming a Septum (*Replum*). Ex. *Matthiola.*
  - 12. *Silicula.* A very short *Siliqua.* Ex. *Thlapsi.*
  - 13. *Ceratium.* A *Siliqua* in some *Fumariaceæ* and *Papaveraceæ.*
  - 14. *Rhegma.* Elastically two-valved (?), dehiscing from a *Columella.* Ex. *Euphorbia.*
  - 15. *Capsula.* One-celled or many-celled, many-seeded, dehiscing by valves or pores, *Primula*, *Antirrhinum.*
  - †† Inferior.
  - 16. *Diplotegia*, Desvaux. Inferior capsule, dehiscing by pores. Ex. *Campanula.*
- *B.* Splitting Fruits (*Schizocarpium*).
  - 17. *Cremocarpium* (?). In *Umbelliferæ*, *Rubiaceæ.*
    - *a. Mericarpia.* The separate parts of the *Schizocarpium.*
  - 18. *Carcerulus.* In *Tropæolaceæ*, *Malvaceæ.*
  - 19. *Achænium.* In *Boraginaceæ*, *Lamiaceæ.*
- *C.* Stone Fruits (*Drupa*).
  - 20. *Drupa.* Originally one-celled, 1-seeded, 2-seeded. The *Mesocarpium* fleshy, the *Endocarpium* woody. Ex. *Amygdalus.*
  - 21. *Tryma*, (imagined to be) one-celled by suppression in *Juglans.*
- *D.* Berry (*Bacca*).
  - 22. *Bacca.* Many-celled, inferior. Ex. *Ribes.*
  - 23. *Nuculanium.* Many-celled, superior. Ex. *Vitis.*
  - 24. *Pepo.* One-celled, inferior. Ex. *Pepo.*
  - 25. *Hesperidium.* Coriaceous portion, strictly separated from the pulp. Ex. *Citrus.*
  - 26. *Amphisarca.* Woody toward the exterior. Ex. *Crescentia.*
- *E.* Closed Fruit (*Achænium*).
  - 27. *Achænium* (*Auctorum*), *Cypsela* (Lindley). One-celled, one-seeded, not blended with the seed. Ex. *Compositæ.*
  - 28. *Glans.* Through abortion one-celled, one-seeded. Ex. *Corylus.*
  - 29. *Caryopsis.* One-celled, one-seeded (imagined to be) blended with the seed. Ex. the Grasses.
  - 30. *Samara.* Two-celled, winged. Ex. *Acer.*
  - 31. *Carcerulus.* Many-celled, not winged. Ex. *Tilia.*

III. Multiple Fruits (*Fructus multiplex*).
- *A.* Several Achænia.
  - 32. *Etærio.* If wholly free. Ex. *Ranunculus.*
  - 33. *Syncarpium.* If connected. Ex. *Magnolia.*
- *B.* Several Berries.
  - 34. *Etærio.* Connected. Ex. *Rubus.*

IV. Fructifications (*Fructus compositus*).
- *A.* *Capitula.* With a flat or cup-shaped fleshy peduncle.
  - 35. *Syconus.* Ex. *Ficus*, *Dorstenia.*

B. Spikes with fleshy bracts and perianths.
36. *Sorosis.* Ex. *Ananassa, Morus.*
C. a. Spikes with woody bracts.
37. *Strobilus.* Ex. *Betula.*
b. Spikes with woody bracts and perianths.
38. *Strobilus.* Ex. *Casuarina.*
V. Spurious Fruits (*Fructus spurius*).
39. *Cynarhodon.* Free one-seeded Achænia, surrounded by a fleshy disc. Ex. *Rosa.*
40. *Pomum.* Many-seeded Achænia in one circle, blended with the fleshy disc. Ex. *Malus.*
41. *Balausta.* Many-seed Achænia in two circles, blended with the fleshy disc. Ex. *Punica.*
42. *Diclesium.* Achænia enclosed in a hardened perianth or corolla. Ex. *Spinacia, Mirabilis.*
43. *Sphalerocarpium.* Achænia inclosed in a drupaceous perianth. Ex. *Hippophäe.*

FUCACEÆ, a natural order of *Algæ*, or olive-coloured inarticulate Sea-Weeds, whose spores are contained in spherical centres, immersed in the substance of the frond. The root has almost always a conical disc, rarely branching or creeping. The fronds are of an olive-brown or olive-green colour, becoming darker in drying; of a tough leathery substance, and fibrous texture, tearing lengthwise with facility; dichotomous or pinnate; rarely irregularly branched, but very variable in habit. In the simpler kinds (*Splancnidium*) there is no distinction into parts (as stem, leaves, receptacle), but the fructification is equally dispersed through all parts of the plant; in others (*Durvillæa, Sarcophycus*) there is a stem ending in a phyllo-caulon or leaf-like frond, through which the fructifications are scattered; in others (*Himanthalia*) there is a simple frond of small size, and a branching receptacle of fructification resembling a frond; in others (*Fucus, Cystoseira*) there is a branching or imperfectly leafy frond, some portions of whose branches finally swell and are converted into receptacles of fruit; and, finally, in the most perfect kinds (*Sargassum, Marginaria*) there is a branching frond, with well-formed mostly distinct and nerved leaves and receptacles, from their origin set apart as organs of fructification (not formed by swellings of the old branches), developed either in the axils or along the edges of the leaves or branches. Air-vessels are present in almost all, either in bladdery swellings of the stem and branches, as in *Fucus*, or as distinct organs, as in *Sargassum*, stalked, and mostly springing from the same part as the fructification. Receptacles of the fruit, mostly more or less distinguishable from the barren portion of the frond, swollen, succulent, often filled with slimy mucus, either formed from the metamorphosed ends of the branches, or evolved from the axils or sides of the branches or leaves. These receptacles are pierced by minute pores, which communicate with small spherical chambers formed by an introflexion of the walls of the receptacle at the points where they occur. The little chambers (called Conceptacles by some writers, Scaphidia by others) contain sometimes spores, or reproductive bodies, analogous to the seeds of more perfect plants; sometimes antheridia, supposed to be analogous with stamens; sometimes both organs in the same chamber. The spores spring from the sides of the chamber. One of the surface-cells being fertilised, gradually enlarges, projects from the wall of the chamber, becomes more or less obovate, and finally is converted into a perispore, or membranous transparent case, in which is contained the spore or spores. These last are formed from the matter contained within the enlarged cell. At first the contents are nearly fluid, of a pale olive colour; gradually they acquire density, become darker, and at length are consolidated into a single sporule, as in *Cystoseira, Halidrys*, &c., or formed into two, four, or eight sporules, as in *Fucus, Himanthalia*, &c. The antheridia are borne on branching jointed threads, called Paranemata, which rise, like the spores, from the walls of the conceptacle, and commonly fill the greater part of its cavity. Each antheridium is an oblong cell, forming the terminal articulation of the branches of the paranemata, and is filled with minute orange-coloured bodies called Sporidia (by J. Agardh), closely resembling the zoospores of the lower *Algæ*, and like the latter endowed with spontaneous movements. The motive organs are vibratory hairs, or cilia, with two of which each little body is furnished.

The *Fucaceæ* are easily known from all other Olivaceous Sea-Weeds by a character at once natural and easily ascertained, namely, the position of their spores within little hollows sunk in the substance of the plant, and communicating with the surface by a pore. The order is represented in most climates, from high northern and southern latitudes to the equator. Very few species vegetate in the polar regions of either hemisphere. In the north the species of *Fucus* and *Himanthalia* alone reach to the Icy Sea; and in the Antarctic Ocean the order is limited to *Durvillæa* and to *Scytothalia Jaquinotii*, a fine *Alga* allied to sub-tropical forms. The British species, excluding three doubtful natives, are but fourteen; yet from the strictly social habits of several of them, they cover more surface of tidal rocks than all the other *Algæ* put together. It is these plants which impart the deep brown colour to the belts of rocks exposed on the recess of the tide.

The following is a synopsis of the British genera of these plants:—

Sargassum.—Branches bearing ribbed leaves. Air-vessels simple.

Halidrys.—Frond linear, pinnate, leafless. Air-vessels divided into several cells by transverse partitions.

Cystoseira.—Root scutate. Frond much branched, bushy. Receptacles cellular.

Pycnophycus.—Root branching. Frond cylindrical. Receptacles cellular.

Fucus.—Root scutate. Frond dichotomous. Receptacles filled with mucus, traversed by jointed threads.

Himanthalia.—Root scutate. Frond cup-shaped. Receptacles (frond-like) very long, strap-shaped, dichotomously branched.

I. SARGASSUM.—Frond furnished with distinct, stalked, nerved leaves, and simple axillary stalked air-vessels. Receptacles small, linear, tuberculated, mostly in axillary clusters or racemes. Seeds in distinct cells. The generic name is from Sargazo, the Spanish term for masses of sea-weed found floating in the ocean in some latitudes.

1. *S. vulgare;* and
2. *S. bacciferum*, though both of them have been found cast on our shores, have no just claim to a place in our British Flora, being natives of the tropics, occasionally driven, with other tropical productions, by the force of the western currents on our Atlantic coasts. The species of this genus are found over a wide extent of ocean, and have been generally called 'Gulf-Weed.' They appear like floating meadows in the midst of the ocean, sometimes for miles in extent, and probably support a larger number of living creatures than the most productive pasturage in Great Britain. Myriads of Mollusks, *Radiata*, Fishes, and *Crustacea* may be seen playing about in these masses; and the abundance of Zoophytes which find shelter in such situations can hardly be estimated. The weed is eaten in China. In the East it is used in salads, and forms a pickle.

II. HALIDRYS has compressed linear fronds, pinnated with distichous branches. The air-vessels are lanceolate, stalked, divided into several cells by transverse partitions. The receptacles are terminal, stalked, cellular, pierced by numerous pores, which communicate with immersed spherical conceptacles.

H. siliquosa has linear very narrow branches, compressed linear lanceolate air-vessels, slightly constricted at the septa, mucronate. It is found on rocks and stones in the sea, at and below half-tide level.

III. CYSTOSEIRA has a frond furnished with branch-like leaves, becoming more filiform upwards. The air-vessels are simple, arranged within the substance of the branch-like leaves consecutively. The receptacles are cylindrical, more or less lanceolate, tuberculated, and terminal. The seeds in distinct cells. The name is derived from two Greek words, signifying a little sac and a chain.

C. ericoides has a thick woody short stem, cylindrical, and beset with numerous slender filiform branches, variously divided, and densely clothed with small spine-like awl-shaped ramuli (or leaves). It is found on rocks in the sea, and has the property of being iridescent when under water in a growing state. In drying it becomes nearly black, and does not adhere to paper.

The other British species of this genus are—*C. granulata, C. fœniculacea, C. barbata*, and *C. fibrosa.*

IV. PYCNOPHYCUS has a root composed of branching fibres. The frond is cylindrical and dichotomous. The air-vessels, when present, innate and simple. The receptacles terminal, cellular, pierced by numerous spores, which communicate with immersed spherical conceptacles, containing in the lower part of the receptacles parietal simple spores, and in the upper tufted antheridia. The name is from two Greek words, signifying thick sea-weed.

P. tuberculatus is found in rock-pools, on the recess of the tide, near low-water mark. It is better known by the name of *Fucus tuberculatus.* It is very different in many respects from *Fucus* proper. When dry it becomes very brittle and black.

V. FUCUS has a plane compressed, or cylindrical frond, linear, dichotomous, coriaceous. The air-vessels, when present, are innate in the frond, simple, and large. The receptacles terminal (except in *Fucus nodosus*), turgid, containing tubercles imbedded in mucus, and discharging their seeds by conspicuous pores.

F. vesiculosus is common on all our sea-shores. It is the Sea-Ware, Bladder-Fucus, Kelp-Ware, Black-Tang of Scotland, and sometimes Lady-Wrack. In Gothland, according to Linnæus, it is Swine-Tang, because boiling it and mixing it with a little coarse flour they give it to their hogs. In the Hebrides, cheeses are dried without salt, being covered with the ashes of this plant, which abounds with salt. In Scania it is used as thatch and fuel. The root is a hard flat disc. The fronds are from 2 to 3 feet in length. The air-vessels, as large as nuts, are in pairs; the receptacles, in pairs, and often forked, terminate in branches. There is a variety of this which is often called *Fucus Balticus.* It is found among grass and moss in marshy ground occasionally overflowed by the tide. Lightfoot mentions that during the snow-storms in the Highlands, the red deer descend from the wild mountains to feed on this sea-weed. He mentions also that the saponaceous mucus of the vesicles has been recommended to remove glandular swellings, and the calcined powder of the plant is said to be valuable as a dentifrice. The great use now made of this weed, as well as of others, is in the manufacture of kelp and iodine.

F. ceranoides is sometimes called the Horned Fucus. It resembles the preceding species, but is much thinner and more transparent, the midrib is more distinct, and the leafy part is narrower, although it is a more graceful plant than *F. vesiculosus*.

F. serratus, Serrated Sea-Weed, is very common on all our sea-shores. It is perennial. The frond differs from the preceding by being serrated. In Scotland it is called Black-Wrack, or Prickly Tang. It is not so rich in kelp and iodine as the others. It is useful as manure. In Norway it is used as food for cattle, mixed with meal. The Dutch use it to cover their crabs and lobsters, to keep them alive and moist, preferring it to any other because it is destitute of that mucus which causes them to ferment and putrefy. It is a handsome species, the fronds on both sides being dotted with pencil-like clusters of whitish capillary fibres, and the fronds being often broad.

F. nodosus, Knobbed-Wrack. The root is a large hard conical mass, from which spring several branches, from 2 to 4 or 6 feet in length. It is called in some places Yellow Wrack. In England it is often called Sea-Whistle, in consequence of the custom among children of converting the vesicles into whistles. The air-vessels are called crackers; for when thrown into the fire they make a slight explosion.

F. Mackaii is found on muddy sea-shores, usually in land-locked bays and among boulders. The frond is from 6 to 10 inches long, densely tufted; branches crowded, spreading, compressed at the base, cylindrical upwards. The vesicles wider than the frond. In substance leathery; when dry somewhat horny.

F. canaliculatus, Channelled Fucus. This is abundant on rocks on the sea-shore near high-water mark. It is perennial. Cattle are exceedingly fond of it, and never fail to browse on it in winter as soon as the tide leaves it within their reach.

VI. Himanthalia has coriaceous orbicular top-shaped fronds. Very long strap-shaped receptacles, repeatedly forked, spring from the centre of the frond, filled with mucus, traversed by jointed fibres, and pierced by numerous pores, which communicate with immersed spherical conceptacles, containing either parietal spores or antheridia.

H. lorea is common on rocky sea-shores. It seems difficult to determine as to the duration of this plant. Some regard it as annual, as the thongs are produced every year; but others say the long thongs are only receptacles, that the cup-shaped disc is perennial, and that this part is truly the plant. The cup-shaped frond which adheres firmly to the rock is more than an inch in diameter. The branches or receptacles are in Scotland about 6 feet long. In Cornwall they are sometimes 20 feet long. The name in English signifies sea-thongs. The fruit consists of tubercles immersed in the fronds, and these tubercles discharge their seeds by pores, which give the thongs a spotted appearance. This is remarkably the case when, after lying on the shore for some time, every pore is covered with a yellow dot, which is the mucus of the plant discharged in the death-struggle which goes on, when, torn from the rock and tossed out by the waves, it lies withering in the open air. Dr. Neill mentions that in the north of Scotland a kind of sauce for fish or fowl, resembling ketchup, is made from the cup-like or fungus-like fronds of this sea-weed.

(Harvey, *British Marine Algæ*; Landsborough, *British Sea-Weeds*.)

FUCHSIA, a genus of Plants belonging to the natural order *Onagraceæ*. This genus was named after Leonard Fuchs, one of the earliest of modern cultivators of botany. He was born at Wembdingen, in Swabia, in 1501, where he kept a school, but was made a professor at Ingoldstadt in 1521, whence he removed to Anspach, and subsequently to Tübingen, where he died in 1556. He wrote a great work on Botany, with the title 'De Stirpium Historia Commentarii Insignes,' which was published in folio at Basle in 1542. This work was illustrated with wood-cuts executed by Spücklin of Strassburg. These engravings are admirably done, and some of them would bear comparison with the wood-engravings of the present day. This work has been translated into almost every European language, and many editions of the original Latin have been published. It was however only a part of a great work which the author had on hand; and when he died he left about 1500 drawings, with which he had intended to illustrate a second and third part.

The genus *Fuchsia* has the tube of the calyx adhering to the ovarium at the base, and drawn out at the apex into a cylindrical 4-cleft tube, whose lobes soon fall off; four petals alternating with the lobes of the calyx, and inserted in the upper part of the tube, very rarely wanting; eight stamens; the ovary crowned by an urceolate gland; the style filiform, crowned by a capitate stigma; the berry oblong or ovate-globose, 4-valved, 4-celled, many-seeded. The species are shrubs, usually with opposite leaves, and axillary 1-flowered pedicels, which are sometimes disposed in racemes at the tops of the branches. The flowers, which are very elegant, are usually drooping, of a red colour, rarely white, sometimes 5-cleft, and decandrous. There are few genera of plants in which, under cultivation, there is a greater tendency among the flowers to sport; and thus they frequently afford the most interesting and important illustrations of the doctrines of morphology.

F. microphylla, the Small-Leaved Fuchsia, has pubescent branches, with opposite, small, elliptic-oblong, acutish, toothed, glabrous, a little ciliated leaves; the pedicels axillary, shorter than the flowers; the calyx funnel-shaped, with ovate-acuminated lobes; retuse toothed petals. This plant is a native of the volcanic mountain Jorullo, in Mexico. It has a scarlet calyx, with deep red petals, and blossoms from June to September. It was first described by Humboldt, Bonpland, and Kunth, in their work on American Plants, and was first introduced into England in 1828. It is now one of the most commonly cultivated of the species in the gardens of Great Britain.

F. coccinea, the Scarlet Fuchsia, has glabrous branches, opposite leaves, or three in a whorl, ovate, acute, denticulated, on short petioles; the pedicels axillary, drooping, longer than flowers; the lobes of the calyx oblong, acute, exceeding the petals, which are obovate and convolute. It is a native of Chili, in marshy districts, and is found as far south as the Strait of Megalhaens. It is one of the species earliest introduced into the gardens of Great Britain; and was first described by Aiton in the 'Hortus Kewensis.' It has a scarlet calyx, with violaceous petals. In its native countries the wood is used for obtaining a black colouring-matter, and the leaves and young branches are used as medicine. It grows and blossoms in the open air in the summer, but requires protection in the winter.

F. corymbiflora (*corymbifera*, Walpers), the Corymbose Fuchsia, has branches somewhat tetragonal; leaves opposite, petiolate, oblong lanceolate, almost entire; the pedicels three, nearly terminal, nodding, shorter than the flowers; the lobes of the calyx lanceolate-acute, twice the length of the petals, which are oblong-lanceolate. This elegant shrub is about 6 feet in height, and is a native of Peru about Chincao and Muna, in shady groves. It has scarlet flowers 2 inches long, which hang down in beautiful corymbs. The berries are ovate-oblong, of a reddish-purple colour. This plant, although described by Ruiz and Pavon, was only introduced into our gardens about the year 1838, and is now justly considered the most ornamental species of this beautiful genus.

F. arborescens, the Arborescent Fuchsia, has glabrous branches, the leaves three in a whorl, oval-oblong, acuminated at both ends, petiolate, quite entire; the panicle terminal, trichotomous, nearly naked; the calyx funnel-shaped, with the lobes ovate, acute, and spreadingly reflexed, also the petals. It is a native of Mexico, and has been introduced into this country since 1824. It is a larger plant than most of the species, not unfrequently attaining a height of 15 feet.

F. gracilis, the Slender Fuchsia, has the branches finely pubescent; the leaves opposite, glabrous, on long petioles remotely denticulated; the pedicels axillary, nodding, as long as the calyx; the lobes of the calyx oblong-acute, exceeding the petals, which are convolute and retuse; the stigmas undivided. This plant was first described by Lindley, and has been grown in this country since 1823. The flowers have a scarlet calyx and purple petals.

About fifty species of *Fuchsia* have been described, and many more than those named above have been introduced into the gardens of Europe. They are all American plants. They thrive well in a rich light soil; and young cuttings of them strike root readily in the same kind of soil when covered over with a hand-glass. Many will grow in the open air in this country throughout the winter with a very slight protection. When planted in clumps on lawns or borders they should be mulched at the root to preserve them through the winter. In the spring, when the ground is cleared, the stems of the preceding year, which are generally dead, should be cut off quite close to the ground, to allow the young shoots to spring from the root.

(Don, *Dichlamydeous Plants*; Walpers, *Repertorium Botanices Systematicæ*, vol. ii.; Bischoff, *Lehrbuch der Botanik*.)

FUCHSITE, a Green Mica from the Zillerthal, containing 4 per cent. of oxide of chromium. From the crystallisation of mica, two additional species have been made out of the old species so called. The common mica has an oblique prism for its primary. Many micas when in perfect crystals have the form of a hexagonal prism, and but one axis of polarisation; this last fact proving the primary to be a regular hexagonal prism. This species is properly distinguished, and has been called hexagonal mica.

FUCOIDÆA. [Pseudozoaria.]

FUCOIDES, the vague title for many Fossil Marine Plants, given by Brongniart. They are mostly referred to other genera by later writers. There is a peculiar geological interest in the distribution of Fucoids, since Dr. Forchhammer ('Reports to the British Association,' 1844) has shown the probability of their influence in the metamorphism of rocks.

FUCUS. [Fucaceæ.]

FULGORA, a genus of Hemipterous Insects, popularly known as Lantern-Flies, on account of their power of emitting light in the dark. The *Fulgora laternaria* of Linnæus is the type. It is a native of South America. The form of this insect is very remarkable, on account of the regular inflated and enormous head, out of which the phosphorescence was said to proceed. The celebrated Mademoiselle Merian was the first naturalist who observed this property, and in her great work on the Insects of Surinam she gives an account of her discovery. Strange to say, however, many travellers deny altogether the luminosity of the Lantern-Fly, whilst others as strongly assert it. It is probably a sexual peculiarity, and only exhibited at certain periods in the animal's life.

FULGURITES are vitrified sand-tubes, supposed to have originated from the action of lightning; they are called by the Germans Blitzröhre.

These tubes were discovered in the year 1711 by the pastor Herman, at Massel, in Silesia; and they were again discovered in 1805 by Dr. Hentzen, in the heath of Paderborn, commonly called the Senne, and he first attributed their formation to the agency of lightning.

These tubes have since been found in great numbers at Pillau, near Königsberg, in Eastern Prussia; at Nietleben, near Halle on the Saale; at Drigg in Cumberland, and some other places.

At Drigg, the tubes were found in the middle of sandbanks, 40 feet high, and very near the sea. In the Senne they were most commonly found on the declivities of mounds of sand, about 30 feet high; but sometimes in cavities, which are stated to have been hollowed in the heath, in the form of bowls, 200 feet in circumference, and 12 to 15 feet in depth.

These tubes are nearly all hollow. At Drigg their external diameter was $2\frac{1}{2}$ inches; those of the Senne, reckoning from the surface, are from one quarter to seven lines internal diameter; but they narrow as they descend lower, and frequently terminate in a point: the thickness of the tube varies from half a line to an inch.

These tubes are usually placed vertically in the sand; but they have been found at an angle of 40 degrees. Their entire length, judging from those which have been extracted, is from 20 to 30 feet; but frequent transverse fissures divide them into portions from half an inch to 5 inches in length.

Usually there is only one tube found at a place; sometimes however, at a certain depth, this tube divides into two or three branches, each of which gives rise to small lateral branches, from an inch to a foot in length; these are conical, and terminate in points, inclining gradually to the bottom.

The internal part of the tubes is a perfect glass, smooth and very brilliant, resembling hyalite. It scratches glass, and gives fire with steel. All the tubes, whatever may be their form, are surrounded by a crust composed of agglutinated grains of quartz, which have the appearance, when examined by a glass, of having undergone incipient fusion.

The colour of the internal mass of the tubes, and especially that of the external parts, depends upon the nature of the sandy strata which they traverse. In the superior beds, which contain a little soil, the exterior of the tubes is frequently black; lower down the colour of the tube is of a yellowish-gray; still lower, of a grayish-white; and lastly, where the sand is pure and white, the tubes are almost perfectly colourless.

That the cause of these tubes is correctly attributed to lightning is shown by some observations presented to the Royal Society, in 1790, by Dr. Withering. On opening the ground where a man had been killed by lightning, the soil appeared to be blackened to the depth of about 10 inches; at this depth, a root of a tree presented itself, which was quite black; but this blackness was only superficial, and did not extend far along it. About two inches deeper, the melted quartzose matter began to appear, and continued in a sloping direction to the depth of 18 inches; within the hollow part of one mass, the fusion was so perfect, that the melted quartz ran down the hollow, and assumed nearly a globular figure.

Professor Hagen, of Königsberg, has made a similar observation. In the year 1823 the lightning struck a birch-tree at the village of Rauschen. On cautiously removing the earth, Professor Hagen found, at the depth of a foot, the commencement of a vitrified tube, but it could not be extracted from the sand in pieces of more than two or three inches in length; the interior of these fragments was vitrified, as usual; several were flattened, and had zigzag projections.

It is also to be observed, that Saussure found on the slaty hornblende of Mont Blanc small blackish beads, evidently vitreous, and of the size of a hemp-seed, which were clearly the effects of lightning. Mr. Ramond has also remarked on the Pic du Midi, in the Pyrenees, some rocks, the entire face of which is varnished with a coating of enamel, and covered with beads of the size of a pea; the interior of the rock is totally unchanged.

FULICA. [RALLIDÆ.]

FULIGULA, FULIGULINÆ. [DUCKS.]

FULLERS' EARTH, a Mineral product, formerly much used in the fulling of cloth, whence it derives its name. It occurs massive, and is usually of a greenish-brown or dull gray colour; sometimes it is nearly of a slate colour. It is opaque, dull, and its specific gravity is 1·8 to 2·2. Greasy and soft, yielding to and polished by the nail. Fracture uneven, earthy; in water it breaks down into a soft pulpy mass. Before the blow-pipe it fuses into a white blobby glass.

It is found at Nutfield, near Reigate, in Surrey, and occurs in regular beds near the summit of a hill, between beds of sand or sandstone, containing fossil wood, cornua ammonis, &c. There are two distinct beds of Fullers' Earth; the upper has a greenish colour, is 5 feet in thickness, and rests upon the other, which has a bluish tint, and is 11 feet thick; in these beds, but especially in the latter, there are found considerable masses of sulphate of barytes, frequently in regular crystals. Fullers' Earth is also found in Kent, Bedfordshire, Bath, Nottinghamshire, and Sussex. It is met with also in Styria, Saxony, and some other places.

According to Dr. Thompson's analysis, this substance consists of—

Silica	44
Alumina	23·06
Lime	4·08
Magnesia	2
Protoxide of Iron	2
Water	24·95
	100·09

Dr. Thomson observes that, allowing the lime, magnesia, and protoxide of iron to be in the state of silicates, and as mere accidental constituents, Fullers' Earth is a hydrous bisilicate of alumina, consisting of two equivalents of silica, one equivalent of alumina, and two equivalents of water.

FUMA'RIA (from the Latin *Fumus*, smoke, in allusion to the unpleasant smell which it exhales; the French, with the same meaning, call it Fumeterre, and hence our English word Fumitory), a genus of plants the type of the natural order *Fumariaceæ*. It has 4 petals, the upper one spurred at the base, 2 sepals, diadelphous stamens, fruit indehiscent and 1-seeded. There are about 12 species of *Fumaria*, which are smooth slender herbs, with small racemose white or purplish flowers.

Corydalis lutea.

1, the two sepals, stamens, and pistil; 2, a longitudinal section of the ovary; 3, a longitudinal section of a seed, showing the ovary: all more or less magnified.

F. capreolata, Rampant Fumitory, has ovate acute sepals, toothed, as broad as the corolla, and half its length; globose emarginate fruit; bracts about a third shorter than the fruit-stalks. It is a climbing plant, and has cream-coloured flowers tipped with red or purple.

F. officinalis, Common Fumitory, has ovate lanceolate sepals, narrower and two-thirds shorter than the corolla, broader than the pedicel; fruit globose, truncate, slightly emarginate; bracts two or three times shorter than the fruit-stalks. It grows in corn-fields and cultivated land throughout the world, and is plentiful in Britain. The flowers are of a pale-red colour, deep-red at the summit, with a green keel to the upper and under petals. The leaves are succulent, saline, and bitter, and the expressed juice is recommended as a remedy in cases of hypochondriasis and cachectic states of the body. It is said to correct acidity and strengthen the stomach. Boerhaave used to prescribe it in black jaundice and bilious affections. It has also gained some reputation as a cosmetic. Dr. Cullen recommends an infusion of the leaves in cutaneous disorders, and he also advises the use of it as a tonic whenever bitter remedies are desirable.

F. micrantha is distinguished by its sepals being orbicular dentate, broader than and nearly half as long as the corolla; fruit globose, slightly pointed; bracts longer than the fruit-stalks. This species is found both in England and Scotland, and has pale purple flowers in dense spikes.

F. parviflora has ovate sepals as broad as the corolla and about two-thirds shorter. It greatly resembles *F. officinalis*, but is smaller in all its parts. The flowers are of a pale-red colour. It is found in Kent, and is also very common in the East Indies, where it is used as a medicine. The leaves have a bitter taste, and Dr. Whitlaw Ainslie mentions it in his 'Materia Medica of Hindostan.' The Mohammedans employ it as a diuretic, and in maniacal cases.

F. Vaillantii has its sepals narrower than the pedicels, and many times shorter than the corolla. Globose fruit, scarcely pointed; bracts about as long as the pedicels. The flowers are mostly white with a purple tip. This is a British species, and is also found in sandy fields in the neighbourhood of Paris and Montpelier.

With the exception of one or two species, this genus seems hardly worth cultivation, having but a weedy and insignificant appearance. Such however as have a climbing tendency, look well if sown under a hedge and allowed to twine amongst the stems and branches.

(Don, *Dichlamydeous Plants;* Babington, *Manual of Brit. Bot.*)

FUMARIACEÆ, *Fumeworts,* a small natural order of Exogenous Plants, consisting of slender-stemmed herbaceous plants, many of which scramble up others by aid of their twisting leaf-stalks. They are rather succulent, with watery juice. Their leaves, which have no stipules, are repeatedly divided till the terminal lobes become small ovate leaflets; their flowers, which are extremely irregular, consist of 2 membranous minute ragged sepals, 2 exterior distinct linear petals, and 2 others, which hold firmly together at the points; there are 6 stamens united into two parcels, and the ovary is a 1-celled case with 1 seed or many seeds, whose placentation is parietal; finally, the seeds consist principally of albumen, in which there ripens a very small embryo. *Fumaria officinalis* is one of the commonest of weeds. Many are objects of cultivation by the gardener for the sake of their showy flowers; all are reputed diaphoretics. They only inhabit the cooler parts of the world, alike avoiding extremes of heat or cold. Two species are found in the Cape of Good Hope. The affinities of the order are with *Droseraceæ, Papaveraceæ, Berberidaceæ,* and *Brassicaceæ.* There are 15 genera and 110 species described.

FUMITORY. [CORYDALIS; FUMARIA.]

FUNA'RIA, a genus of Plants belonging to the natural order *Musci*, or Mosses. It has terminal fruit-stalks, with an oblique double peristome, both the outer and the inner having each 16 teeth, the inner ones opposite to those of the outer. There are three British species of this moss: *F. hygrometrica, F. Muhlenbergii,* and *F. hibernica.*

F. hygrometrica has the leaves very concave, ovate, apiculate, entire, the nerves excurrent; the fruit-stalk curved, flexuose. It is a native of Great Britain, and is found by waysides and under hedges, especially on spots where a wood-fire has been burning on the ground. It may be thus constantly found on the site of gipsies' encampments. It has obtained its specific name *hygrometrica* from its fruit-stalk having the property of twisting in different directions when moisture is applied to it. On taking a dry fruit-stalk into the hand and moistening the lower part with the finger, the capsule will turn itself from the right to the left by making two, three, or more turns; on moistening the upper part in the same manner, the capsule turns itself more rapidly in an opposite direction. Under the microscope the stalk exhibits an elongated cellular tissue twisted in a spiral form. The cellular tissue is not however turned uniformly, but at two-thirds of the length of the stalk it commences to assume a straighter form, and at the upper part it again turns itself, but more acutely, in an opposite direction to that of the lower part. The cause of the turning in two different directions depends on this structure of the cellular tissue. The capsule turns itself in an opposite direction to the spires which are moistened, and the circumstance of its turning more rapidly on the upper end being wetted, depends on the more acute angle made by the upper spires. The dryness of the fibres is not the cause of this phenomenon, as the green fruit-stalks, although perfectly dried, do not turn when moistened. The movements in this case are probably owing to the shortening of the vegetable fibre by the contact of moisture. In the green stalk the thick fluid contents of the cells leave a precipitate when they are dried, which fills them up and prevents the action of moisture upon them. In the ripened stalk this precipitate is dissolved and absorbed, and otherwise applied; and thus the cells, being empty, act like hollow tubes.

(Lankester, *On the Structure of Funaria Hygrometrica; Ann. of Nat. Hist.* vol. iv.; Link, *Report on the Progress of Botany,* 1841, translated for the Ray Society, vol. i.; Hooker and Taylor, *Muscologia Britannica.*)

FUNGI. Under this name botanists comprehend not only the various races of mushrooms, toadstools, and similar productions, but a large number of microscopic plants forming the appearances called mouldiness, mildew, smut, rush, brand, dry-rot, &c. Notice has been occasionally taken of these plants under their respective heads; in this place some general account will be given of them as a large natural order.

Nothing can well be more different than the extremes of development of *Fungi*, if the highest and the lowest forms are contrasted; as for example, the large fleshy *Boleti*, which grow on the trunks of trees, and the microscopic mould-plants, composed of threads much too delicate to be distinguished by the naked eye. Nevertheless, it turns out upon inquiry that the latter is only a simple form of the former, or, in other words, that a *Boletus* is merely an enormous aggregation of the vegetable tissue constituting a *Mucor*, developed upon the same plan, subject to the same influences, possessing a similar chemical character, and propagating by means which are altogether analogous.

Viewed with reference to their whole extent, the plants of this order may be described as cellular or filamentous bodies, having a concentric mode of development, often when full grown almost amorphous, nourished through their thallus (spawn or mycelium), living in air, propagated by colourless or brown spores, and sometimes inclosed in asci and destitute of green gonidia.

That they are cellular or filamentous may be easily ascertained by examining them with even an indifferent microscope; perhaps they might be even simply described as cellular, for their filamentous tissue seems nothing but cells drawn out. Sometimes, as in the genus *Uredo*, they consist of spheroidal cells, having little connection with each other, each cell containing propagating matter, and all separating from each other in the form of a fine powder when ripe: the smut in corn is of this nature; or, as in *Cylindrosporium*, the cells are truncated cylinders not adhering, so far as we can see, and separating in like manner when ripe. In plants of a more advanced organisation, as the genus *Monilia*, the constituent cells are connected in series, which preserve their spherical form, and also contain their own reproductive matter; while in such plants as *Aspergillus* the cells partly combine into threads forming a stem, and partly preserve their spheroidal form for the fructification. (*Fig.* 24.) From adhering in simple series, the structure of *Fungi* advances to a combination of such series into strata, whence result the various kinds of dry-rot—thick leathery expansions developing amidst decaying timber; a more complicated form is thence produced in the form of puff-balls, truffles, sclerotiums, and the like, in which a figure approaching that of a sphere is the result, the reproductive cells being indiscriminately confused in the interior of such plants; and finally, the organisation is so much complicated that, independently of a mere aggregation of tissue, we find envelopes of various kinds for the protection of the propagating mass, as in *Agaricus* and *Geastrum*, and special receptacles for the propagating matter, as in *Boletus* and numerous others.

It is probable however that in all *Fungi*, and certain that in most of them, the first development of the plant consists in what we here call a filamentous matter, which radiates from the centre formed by the spore (or seed), and that all the cellular spheroidal appearances are subsequently developed, more especially with a view to the dispersion of the species. We purposely say dispersion, not multiplication; for it is certain that the filamentous matter is quite as capable of multiplying a fungus as the cellular or spheroidal. This is partly proved by the common Mushroom (*Agaricus campestris*), whose filamentous matter is commonly sold under the name of spawn for the artificial multiplication of that species in gardens; and more completely by some recent experiments of M. Audouin, who found that the *Botrytis Bassiana* would inoculate caterpillars and other larvæ as readily by minute portions of its spawn as by its spores or seed-like spheroidal particles. Although however there seems so much reason to ascribe the presence of a filamentous spawn to all *Fungi*, yet it is seldom seen by the ordinary observer; for it develops out of sight, under ground, in the midst of the decaying matter on which *Fungi* so often appear, or through the very substance of living matter; and it is only the aggregation of spheroidal matter which we see. It would appear that for the growth of the former darkness is necessary, and that the latter is stimulated into existence by the action of a feeble quantity of light. To apply to these parts familiar and equivalent names, we should say that the stalk or stem radiates in dark damp situations where it is buried from sight, and that the spheroidal part or fructification alone is able to develop beneath the light of day. The spawn of the mushroom is its stem; the mushroom itself is the fructification of the plant.

It is generally believed that spiral cells are unknown in *Fungi;* Corda however, in his microscopical work on these plants, figures them in the genus *Trichia*, calling them Elaters, and thus assigning them a nature analogous to that of the organs known by the same name in *Jungermanniaceæ* and *Marchantiaceæ.* They were first detected by the younger Hedwig. Berkeley has also detected them in the genera *Batarrea* and *Podaxon.*

The concentric growth of the filamentous stem or spawn of *Fungi* may generally be witnessed in damp cellars, when they begin to grow without impediment upon the walls or decaying wood. Nothing is more common in such situations than to see a beautiful white flocculent matter, which a breath almost will dissipate, spreading from a centre nearly equally in all directions; such appearances, formerly called Byssi, have been ascertained to be the spawn of various kinds of *Fungi*, the fructification of which is probably never developed. Evidence of the existence of a similar mode of growth may be found when the spawn itself is not visible, as in fields where *Fungi* so often spring up in circles or rings; this arises from their stem having originally spread circularly from its point of origin, and thrown up its fructification at the circumference of the circle so formed.

As *Fungi* spring up in great numbers where there is decaying animal or vegetable matter, it has been supposed that the cells of vegetables or animals grow into these forms of life. But that they are not equivocally generated is sufficiently proved by each species having its own particular kind of seed or spore; a provision that would be perfectly unnecessary if the species sprang up out of decaying matter by the mere action of particular combinations of external forces. To assert the existence of fortuitous creations in this class of plants is contrary not only to analogy but to the plainest evidence. The experimental observer may indeed discover that *Fungi* will regularly develop in one kind of chemical mixture and not in another. Dutrochet, for example, found that, if he acidulated a weak solution of white of egg, different species of *Monilia* rapidly formed upon it; while, if he rendered such a solution slightly alkaline, the genus *Botrytis* made its appearance; and that the solution in its simple state, neither alkalescent nor acidulated, produced no *Fungi*—a remarkable circumstance enough. But it would be too much to infer from such an experiment "that invisible germs of a filamentous plant may be created by the chemical action of an acid or an alkali on organic matter dissolved in water, and that they develop by virtue of the vital action which would be the necessary attribute of the chemico-organic molecular compound." On the contrary, the experiment only showed that the seeds of *Fungi*, like those of other plants, require special soils in which to grow; that *Botrytis* will not grow in acid mucilage, nor *Monilia* in alkaline, nor either in mucilage in a neuter state. This is only what happens in plants of a more highly-organised nature. Who ever saw the horned-poppy of the sea-shore growing spontaneously in an inland field, the marsh-marigold on a dry heath, or the reindeer-lichen of Lapland on a heath in Italy? Let any one take a few different kinds of seeds, and commit them all to the ground in the same place; some will spring up and flourish, others will just appear above ground and then perish, others will make an attempt to germinate. This, an every-day event, is a sufficient explanation of the fact elicited by M. Dutrochet's experiment. Every kind of seed has something specific in its nature, in consequence of which it requires particular kinds of soil, and some special combination of heat, light, and moisture, to be roused into a state of vegetation. As to the presence of the seeds of *Botrytis* and *Monilia* in the vessels in which M. Dutrochet's experiments were conducted, it is perfectly easy to conceive that the seeds of such common plants exist everywhere suspended in the air or adhering to the cleanest vessels; they are so numerous as to baffle all powers of calculation; they are so minute as only to become visible when aggregated in masses of many thousands; and so generally dispersed that it is difficult to conceive a place in which they may not be reasonably supposed to exist. The very general existence of dry-rot is no weak evidence of this. [DRY-ROT.]

Fungi are among the most numerous of all plants in regard to genera and species. Mr. Berkeley gives the number of genera as 598, and the species as 4000; but new forms are constantly being added to those already known. It is generally asserted that they are uncommon in tropical countries, but it is doubtful whether this is true, as recent travellers have brought home collections as well as indicated the existence of many forms in tropical climates.

They usually prefer damp, dark, unventilated places, such as cellars, vaults, the parts beneath decaying bark, the hollows of trees, the denser parts of woods and forests, or any decaying matter placed in a damp and shaded situation; and are most especially averse to dryness and bright light. Even when they appear upon the live leaves of trees, the stems of corn, or in similar situations, it is either at the damp and wet season of the year, late in the autumn, or in damp and shaded places; and M. Audouin has shown experimentally that when live insects are attacked by them it is only when they are confined in damp unventilated places. ('Comptes Rendus,' 1837.) In stations favourable to their multiplication they often commit extensive ravages, attacking and destroying timber, and producing decay in all kinds of vegetable matter of a soft and succulent nature; nor is it to dead matter that their ravages are confined. They sometimes fix themselves upon live insects, producing great havoc among the silkworms in the manufactories of Italy, and are probably the cause of a more extensive destruction of such animals than we at present have any idea of. Under the name of mildew and blight they commit excessive damage among living plants, as the farmer and orchardist know too well to their cost.

There is frequently considerable difficulty in distinguishing *Fungi* from the other forms of Cryptogamic Plants. They are distinguished from Lichens by their more fugitive nature, their more succulent texture, their want of a thallus or expansion independent of the part that bears the reproductive matter, but more particularly in their never containing germs distinct from the fructifying bodies of a vegetable germ so constant in Lichens.

From some forms of *Algæ* they differ very little, but the most obvious distinction is their mode of growth. The *Algæ* like the Lichens do not derive their nutriment from the bodies on which they grow, which is the case with all the *Fungi*. There are however certain free forms of *Fungi* which it is difficult to distinguish from *Algæ* by this character; such are the moulds which are developed in ink, milk, and other liquids.

It has been stated that *Fungi* are distinguished from *Algæ* by the absence of spontaneous movements. It is no doubt true that the condition of the protein which is the motile agent in all plants is different in *Fungi* from what it is in *Algæ*, but this is no general distinction. In those *Fungi* which are developed in water, in one instance at least, the *Achlya prolifera*, or *Saprolegnia ferax* [ACHLYA; SAPROLEGNIA], the movements of the spores are as active as in any of the *Algæ*.

"In the simplest form *Fungi* are little articulated filaments composed of simple cellules placed end to end. Such is the mouldiness that is found upon various substances, the mildew of the rose-bush, and in short all the tribes of *Mucor* and *Mucedo*. In some of these the joints disarticulate, and appear to be capable of reproduction; in others spores collect in the terminal joints, and are finally dispersed by the rupture of the cellule that contained them. In a higher state of composition *Fungi* are masses of cellular tissue of a determinate figure, the whole centre of which consists of spores attached, often four together, to the cellular tissue, which at length dries up, leaving a dust-like mass intermixed more or less with flocci, as in the puff-balls, or sporidia, contained in membranous tubes or asci, like the thecæ of Lichens, as in the Sphærias. In their most complete state they consist of two surfaces, one of which is even and imperforate, like the cortical layer of Lichens; the other separated into plates or cells and called the hymenium, to whose component cells, which form a stratum resembling the pile of velvet, the spores are attached by means of little processes, and generally in fours, though occasionally the number is either less or greater." (Lindley.)

The following is Schleiden's account of the development of the organs of reproduction in the *Fungi*:—

"The most simple (*Hyphomycetes*, filamentous *Fungi*) form, at the end of the thread-like cells, narrower protuberances, in each of which a spore is developed: this at length separates, having consequently a double membrane, the cell of the spore itself and the covering (sporangium) arising from the parent cell, as, for instance, in *Penicillium* and *Botrytis*. In others the thread-like cells form a spherical swelling at the extremity, from which project a number of such prolongations, each of which contains a spore, while the whole forms a divided sporangium, as for instance, in *Mucor* and *Penicillium*.

"In others (*Gasteromycetes*, the ventricular *Fungi*) the thread-like cells combine into pointed, or non-pointed, variously-shaped sporocarps; in or upon which are spores, of the development of which we know nothing. After the scattering of the spores, the thread-like cells often remain as tender wool, as in the *Trichiaceæ*, or as a delicate network (capillitium), as, for instance, in *Stemonitis*, *Cribraria*; and the external capsule (uterus peridium) generally composed of fine filamentous cells, is then dissolved, or bursts in different regular ways, as in *Arcyria* and *Geastrum*.

"In the most highly developed *Fungi* (*Hymenomycetes*, membranous *Fungi*), elongated pouch-like cells (probably only the ends of the interwoven filiform fungus-cells, developed into the sporocarps, or cells formed at the ends of these cells) combine by arrangement side by side so closely as to form a membrane (hymenium). Some of the cells of this membrane enlarge considerably (sporangia), and send out from one to six points at their free extremity, in each of which a spore is developed. The filiform cells of the fungus then either form round masses, closed in all round (sporocarps), with cavities in their interior, the walls of which are clothed by the hymenium, or they form definitely arranged columns in *Merisma*, tubes in *Polyporus*, or lamellæ in *Dædalea* and *Agaricus*, which are clothed by the hymenium, as in the *Hymenomycetes*. Of the latter we only know, with any amount of accuracy, the law of development relating to the Toadstools, and more especially that of the *Agaricineæ*. In these latter there are formed, at definite parts of the flocculent mycelium, small hollow heads (volvæ), at the bottom of the cavity of which there grows a corpuscle, shortly pedunculated below, and enlarged into a spherical form at the top. In the lower part of this protuberance a horizontal circular cavity is formed, to the upper surface of which are attached the tubes, lamellæ, &c., which bear the hymenium. The bottom of the cavity is only formed by a membrane (indusium), which is either separated from the pedicel on its further development, or, loosening itself from it and the upper part at the same time, remains as a membranous ring (annulus) upon the stalk. The upper part, which supports the hymenium on its lower surface, dilates subsequently, and appears as an umbrella-like expansion, called the cap (pileus). The whole then breaks through the volva, which is very soon dissolved."

During their growth the same *Fungi* assume very different forms and appearances. It thus happens that the same species has not only been described under different specific names, but even referred to different genera. Fries states that he has traced no less than eight genera of different authors to mere degenerations or imperfect states of *Thelephora sulphurea*. Nees von Esenbeck also states that the same fungoid matter which produces *Sclerotium mycetospora* in the winter, developes *Agaricus volvaceus* in the summer. Professor Henslow has also shown that some of the supposed species of *Uredo* are forms of *Puccinia*, *Aregma*, &c. Kützing, in an essay on the 'Transformations of Plants,' carries his views on this subject very far, and maintains that according to different circumstances the same species will produce *Algæ*, *Fungi*, Lichens, or Mosses.

In the article ENTOPHYTA will be found an account of the plants growing on man and living animals. Many of these are *Fungi*. Professor Balfour, in his 'Class-Book of Botany,' gives the following account of diseases in plants produced by *Fungi*:—

"The attacks of Parasitic *Fungi* cause extensive injury and disease in plants. Some think that the spores of *Fungi* coming into contact with the plant act both as the predisposing and exciting cause of disease; others, perhaps more correctly, think that some change is first produced in the cells of the plant, which enables the spores to find a nidus, and then the disease goes on rapidly, assuming a peculiar type on account of the presence of the fungus: in the same way as vegetable organisms found in diseases of the skin are not to be looked upon as the origin of the disease, but as being developed in textures previously morbid, and as giving often a peculiar character to the disease. Many of the diseases of cultivated crops are attributed to *Fungi*. The spores of *Fungi* are very minute, and are constantly floating in the air. They can easily be applied to the surfaces of plants. When they find an appropriate soil they send out extensive filiform ramifications, which spread under the epidermis of plants, raise blisters, and finally burst forth in the form of orange, brown, and black spots, constituting the fructification. They attack the stem, leaves, flowers, and fruit. Different species are restricted to different plants, and even to different parts of the same plant. The forms which the same fungus assumes seem to vary sometimes according to the plant on which it grows. The disease called Bunt, Smut-Balls, or Pepper-Brand, is occasioned by the plant called *Uredo caries* by De Candolle, and *Uredo fœtida* by Bauer. It attacks the grains of wheat, and may be detected in them in their earliest state. It consists of extremely minute globules of a dark colour, at first attached to a thread-like matter or mycelium. Bauer estimates the diameter of each of the globules at 1-1600th of an inch, and consequently a grain of wheat (reckoned at less than 1-1000th of a cubic inch) would contain four millions such spores. The spores, or powdery matter, have a disgusting odour; hence the specific name given to it. The disease is propagated by contact. Steeping the grain is recommended by some as a means of prevention, and alkaline solutions have been suggested as a remedy. *Uredo linearis*, which is met with also in this disease, is considered as being a young state of the Mildew-plant. Another disease called Smut, or Dust-Brand is caused by a fungus called *Uredo segetum*. It resembles the Bunt-fungus in colour and shape, but its spores are not half so large, and it does not possess a fetid odour. This fungus destroys the ear of corn by first causing the innermost parts of the flower to become abortive, while the pedicels on which these are seated swell and become very fleshy. The fungus then consumes the whole of this fleshy mass, and at length appears between the chaff-scales in the form of a black soot-like powder. It is said also to attack the stem and leaves. When ripe the spores burst through the epidermis, and are dispersed in the form of a black powder like charcoal. The spore is 1-2800th of an inch in diameter. Smut is rare in wheat; it is common in barley, and more so in oats. It is also seen in many grasses, such as *Arrhenatherum avenaceum*. The disease denominated Rust, Red Rag, Red Robin, and Red Gum, is caused by a fungus called *Uredo rubigo*. It forms yellow and brown oval spots and blotches upon the stem, leaves, and chaff. The spores burst through the epidermis and are dispersed as very minute grains. The disease is common in corn and in grasses. Mildew is a disease caused by a fungus denominated *Puccinia graminis*. The ripe spore-cases of this plant are small dark brown club-shaped bodies, their thicker end being divided into two chambers, each filled with minute spores, and their lower end tapering into a fine stalk. The sori, or clusters of spore-cases, burst through the epidermis sometimes in vast numbers. The minute spores seem to enter the plant by the stomata. Some think that they, as well as other minute spores, are absorbed by the roots. The disease attacks wheat. Spring wheat is less liable to this disease than winter wheat, and heavy soils are less subject to it than light ones. Many have supposed that the Barberry is in some way connected with the production of Mildew. This idea has been proved to be erroneous by the experiments of Staudinger, near Hamburg, and of Hornemann at Copenhagen. Unger entertains the idea that blight, mildew, and smut are to be considered as exanthematous diseases of plants caused by the spores of *Fungi* entering the stomata.

"Henslow has shown by experiment, that if the diseased seeds of wheat be steeped in a solution of sulphate of copper they will not produce diseased grain, and that the sulphate of copper does no injury to their germination. The solution used is one ounce of sulphate of copper to a gallon of water for every bushel of wheat. Grain also steeped in hot water does not reproduce these fungoid diseases. In East Lothian, with the view of preventing smut, seed-wheat is often steeped in stale urine, and afterwards some newly-slaked lime is sifted on it. Sometimes a solution of salt is used as a pickle. Fourcroy and Vauquelin ascertained by analysis that blighted wheat contained an acrid oil, putrid gluten, charcoal, phosphoric acid, phosphate of ammonia and magnesia, phosphate of lime, and no traces of starch. As regards Bunt or Pepper-Brand, Henslow remarks, that upon simply immersing the grain in water the infected seeds float, and on the water being poured out, nothing but the sound ones remain in the vessel. This simple process of separation is not however perfectly effective, because in thrashing the wheat many of the infected grains are crushed, and the spores are dispersed in the form of fine powder which adheres obstinately to the sound grain, by means of an oily or greasy matter found in the *Fungi*. In order to detach them thoroughly it has been considered useful to add some alkaline ley to the water in which they are washed. The alkali unites with the oil and forms a soapy matter. Lime has been used for this purpose, common potash, substances containing ammonia, and the liquid from stable dung have also been employed; other matters, as sulphate of copper, act by destroying the vegetating powers of the *Fungi*.

"Mr. Ellis, of Barning, Kent, says that the invariable prevention of smut in wheat is accomplished by scalding the blackest wheat in boiling water, and afterwards dying it with lime. The wheat placed in a colander or in a basket is immersed in boiling water for a few seconds, just long enough to wet it completely, it is then immediately dipped in cold water, afterwards dried with lime, mixed with other wheat, and sown. By this means the wheat was always found to be cured of smut, while the vegetating principle was uninjured, great care being taken that the water was boiling, and the wheat taken out of the water as soon as completely wetted. Mr. Ellis tried an experiment on a bushel of the blackest wheat he could procure, which he divided into sixteen equal parts, sowing them all the same day, but with different treatment. The result at harvest was that the wheat sown without preparation produced 33 black ears out of every 100, while that dipped in boiling water and limed had not a black ear in several thousands which were examined. Many other species of *Uredo* as well as *Ustilago* give rise to diseases. They receive their names from the plants on which they are parasitic, and it seems probable that the same species presents various forms according to the situation in which it grows. *Ustilago Maydis*, a maize smut, is a fungus which gives rise to protuberances on different parts of the maize. The stem, upper leaves, and especially the bracts become immensely swollen when attacked by this disease, and the ovaries, ovules, and male blossoms are not exempt. The parts affected are at first white tinged with red, smooth, and juicy. The cellular tissue increases in volume, and is permeated by radiating hues consisting of mycelium and spores. The spores are twice as large in linear measure as those of the oat smut. At first the small balls contain a dark strong-smelling fluid, but ultimately the masses become dry, and present a quantity of dark dust mixed with irregular threads. *Ustilago vittata* causes disease in grasses in India. The spores of *Ustilago hypodytes* also cause disease in grasses. The spores are black and round, and the disease they occasion is denominated grass-smut. The plant is described by Tulasne. According to Leveillé, the immense quantity of black dust resulting from it in the hay-fields of France produces injurious effects on the haymakers. A species of *Depazea* or *Septoria* sometimes produces disease in the knots of wheat. Various species of *Erysiphe*, such as *E. guttata*, *E. penicillata*, *E. graminis*, *E. adunca*, and *E. bicornis* give rise to kinds of mildew. Erysiphes are often met with in common pea crops. Some say that Oidiums are merely particular states of Erysiphes. The plant producing mildew in the vine is *Oidium Tuckeri* of Berkeley. Other species of *Oidium* probably cause mildew in the peach, rose, hop, pea, and onion. For destroying the mildew in vines sulphur is recommended to be dusted on them. Some also use a solution of hydro-sulphate of lime, made by boiling sulphur and lime in water. A fungus called *Rhizoctoma Mali* is said to grow on the roots of apples, pears, and quinces, and to cause destruction to the trees. Ergot is a monstrous state of the grain in which the enlarged and diseased ovary protrudes in a curved form resembling a cock's spur, hence the name from the French 'ergot,' meaning a spur. The ovary is black externally, spongy internally, and contains much oily matter. Some consider it as produced by the attack of a fungus, which induces a diseased condition in the ovarian cells. The disease is usually met with in rye, and the name of spurred rye is applied to it. It sometimes occurs in wheat and in barley, and it has also been noticed in *Lolium perenne*, *L. arvense*, *Festuca pratensis*, *Phleum pratense*, *Dactylis glomerata*, *Anthoxanthum odoratum*, *Phalaris arundinacea*, and *Alopecurus agrestis*. Ergot consists of a very dense tissue formed by polygonal cells, united intimately with one another, and filled with an oily fluid. It is developed in the unimpregnated ovule of rye, for although extremely dilated by the entophyte and rendered difficult of recognition, the integuments of the ovule increase without completely losing the form which they would have assumed, if they had grown into a true grain, imitating in this respect the ovaries of wheat, in which *Tilletia Caries* (Bunt) has replaced the seed. The solid mass which has been called *Sclerotium clavus* by De Candolle, and the filamentous portion called *Sphacelia* by Leveillé and Fée, and *Ergotætia* by Quekett, are only properly speaking organs of vegetation. The fungus destined to grow from this apparatus is an elegant *Sphæria*, probably that called by Fries *Cordyliceps purpurea*. This plant has been seen by Schumacher in diseased cereal grains, and it has been detected by Roussel in *Sclerotium clavus*, growing on *Bromus sylvaticus* and *Arundo calamagrostis*, and by Dumeril in Ergot of Rye. Tulasne has shown that this *Cordyliceps* is produced from the Ergot when it is allowed to vegetate. Ergot of Grasses and Ergot of *Cyperaceæ*, according to Tulasne, do not belong to the same vegetable species. Rye affected with this disease, when used as bread, is very prejudicial. The Abbé Tessier showed that Ergot caused gangrene in animals that fed on it, and many instances are recorded of gangrene of the extremities occurring in persons who had lived on diseased rye. Ergot is said to prevail in rye grown on wet and stiff land.

"The disease which has recently attacked the Potato in various parts of the world is by many attributed to the attack of *Fungi*. This view has been strongly advocated by Berkeley, who describes the fungus as *Botrytis infestans*. The spores are supposed to enter the stomata and to cause disease in the leaves in the first instance, which afterwards extends to the tubers. The effects produced on the leaves resembled much those caused by poisonous gases, such as hydrochloric, sulphuric, and nitric acids.

"Berkeley attributes the Potato disease entirely to *Fungi*. He states that the disease commenced in the leaves. They were attacked by the mould, which ran its course in a few hours; and from the rapidity of the action, the period for examination of the leaves has often passed over. The fungus generated does not live on decayed or decaying matter, but is one which produces decay, and renders the plants unhealthy. The fungus acts by feeding on the juices of plants, preventing the elaboration of the sap in the leaves, obstructing the admission of air and the emission of transpired fluids. The stem is thus overcharged with moisture, and ultimately rots, while every source of nutriment is cut off from the half-ripe tubers. The atmospheric conditions during the late disease made the fungus spread rapidly.

"While there is no doubt that the *Botrytis* is developed in the progress of the Potato disease, the question arises whether or not it is the originating cause. The view which seems to be most consonant with the phenomena is, that changes are induced in the cells of the potato by cultivation which render the leaves liable to disease. Atmospheric influences are thus enabled to act upon them, so as to cause alterations in their cells; and the attack of a fungus, such as the *Botrytis*, accelerates the morbid action, and causes it to assume a peculiar form. In this way high cultivation, atmospheric influences, and *Fungi*, all contribute to cause disease. In the Potato disease of 1845, Harting says that brown granular matter was deposited in the cells, first in those near the epidermis, then the cellular walls lost their transparency, and the cellules could no longer be isolated by boiling water; next the cell-wall was destroyed, and small cavities were formed in the midst of the tissue, in which were agglomerated grains of starch, and finally parasitic organisms appeared in the cavities. Tho vegetable parasites developed were *Polyactis alba. Fusisporium Solani*, *F. didymum*, *F. candidum*, and *Oidium violaceum*. When the disease had advanced insects were also present.

"Crum attributed the disease of the tubers of the Potato to rupture of the starch-cells, and mixture of their contents with nitrogenous matter, thus causing fermentation, as in the Apple and Grape. Solly objects to the fungus theory of the Potato disease. He says that decaying organic matter is necessary for the growth of *Fungi*. He thinks that the disease is caused by the presence of putrifying azotised matter in the stem, just below the surface of the soil; that this is carried to all parts of the plant, causes a struggle between vital and chemical forces, and induces decomposition by a process of fermeutation. The azotised matter, in a condition to act as ferment, is produced by the state of the season, by deficiency of light, and by other meteorological causes. Analyses show that the constituents of the diseased potato undergo a rapid and important change. Dr. Lyon Playfair and Mr. Phillips found that the amount of albumen and gluten decreased from 2·34 in the sound potato to ·32 in the diseased; and when the disease advanced they finally disappeared.

"Mitscherlich says that the change which cellulose undergoes by the action of a peculiar ferment is characteristic of the substance. This fermenting ageut is obtained when half putrid potatoes cut up into pieces are placed in water, with portions of fresh potatoes, and allowed to stand till the cells of the fresh portions begin to be easily separable. It is also formed, though more slowly, when fresh potatoes cut up are set aside covered with water; the liquid is filtered, and fresh potatoes, cut in slices, added to it; when these are decomposed, a portion of the liquid may be treated with water, and more slices of potato added, which soon become decomposed, and in this manner increase the activity of the liquid. Hence, just as in the fermentation of an infusion of malt, the yeast, the fermentative fungus, becomes augmented, so does the ferment increase. It only acts upou the cellulose, which forms the walls of the starch-cells of the Potato; first the cells separate from each other, so that it furnishes us with a convenient means of obtaiuing the cells with their contents in an isolated state, and facilitating their examination; the walls of the cells are subsequently also dissolved, and the starch-particles fall out: in this manner, in 24 hours, a slice of potato is rendered so soft to a depth of two lines that this portion can be removed by a pair of forceps, the hard mass of the potato lying beneath the softened layer, so that this process takes place successively from the outside towards tho interior; not by the whole of the potato being simultaneously permeated by the ferment to the innermost portion. Exactly the same process as that which we can produce spontaneously, he says, occurs in the Potato disease, which during late years has done so much mischief. In this also the cellulose, and not the starch, is decomposed; and the liquid, which the author had kept for a long time in contact with one of the diseased potatoes, immediately produced the decomposition of a sound one. This decomposition is therefore, he says, not the disease itself but merely the result of it. Its cause undoubtedly depends upon the dying or the previous death of the entire plant, and just as it is well known in the case of other plants that they die when the apices of their roots are too strongly cooled, so may a sudden cold rain following a long warm winter produce a similar condition of the potato plant. It is only after decay has commenced that *Fungi* and insects attack the plant.

"Liebig attributed the Potato disease to diminished or suppressed transpiration, depending upon the hygrometric state of the atmosphere. He refers to Hale's accurate researches in regard to the Hop blight, in which the disease is traced to the want of correspondence between absorption and transpiration, and a consequent stagnation and decomposition of the juices. The same thing, he thinks, takes place in the potato in consequence of cold and an atmosphere loaded with moisture; aud he shows that in 1845 and 1846, when the disease overran Europe, damp, cold, and rainy weather followed heat and drought just at the period of the most luxuriant growth of the potato. The vessels and cells became charged with fluids; and, owing to the checked transpiration, there was stagnation of the sap and death.

"*Fungi* and putrefaction are, according to him, the consequences of the death of the plant. Klotzsch proposes to check the Potato disease by pinching off the extreme points of the branches and twigs to the extent of half an inch dowuwards when the plants have attained the height of six or nine inches above the soil, and to repeat this on every branch or twig on the tenth or the eleventh week. This check to the stem and branches, he thinks, will direct the nutrient matters in the direction of the increase and multiplicatiou of subterranean as well as aërial branches. This leads to iucreased development of tuber, aud strengthens the leaves and stalks. Tombelle Lomba, of Namur, says that he has saved potatoes from disease by cutting off the stems after flowering with a very sharp sickle, and then covering the ground with earth to the depth of not less than an inch and a half. The top dressing thus applied was not disturbed till the potatoes were ripe. The haulm was removed after beiug cut. It is said that the tubers acquired a good size and were of excellent quality. If these facts are true, it would appear that while leaves are necessary to the development of tubers the latter on acquiring a certain size can continue their growth by their own proper and unassisted vitality. The general conclusions to be drawn from all that has been said relative to the Potato disease are, that ohanges are induced in the cells and vessels of the potato by certain obscure meteorological and epidemic causes; that an alteration takes place in the cellulose and in the contents of the cells, which speedily leads to decay; that parasitic *Fungi* find a nidus in the decaying organic matter, so as to accelerate and give a character to the disease; and that, as yet, no remedy has been devised."

For an account of the *Fungi* supposed to produce Dry-Rot in timber see the article DRY-ROT.

In many parts of the world the *Fungi* afford a supply of food to the inhabitants, although not more than half a dozen species aro to be found in the markets of London, and only the common Mushroom, Truffle, and Morel are eaten in Paris; in Italy and other parts of Europe a large number of species are consumed. [AGARICUS.]

Dr. Badham, in his work on the 'Esculent Fuuguses of England,' gives descriptions and drawings of the following species of British *Fungi* as those which may be used as food :—

Agaricus aeris minor, *A. alutaceus*, *A. atramentarius*, *A. campestris*, *A. castaneus*, *A. caudicinus*, *A. comatus*, *A. deliciosus*, *A. emeticus*, *A. exquisitus*, *A. fusipes*, *A. heterophyllus*, *A. melleus*, *A. nebularis*, *A. orcella*, *A. oreades*, *A. ostreatus*, *A. personatus*, *A. piperatus*, *A. procerus*, *A. prunulus*, *A. ruber*, *A. rubescens*, *A. sanguineus*, *A. vaginatus*, *A. violaceus*, *A. virescens*, *A. virgineus*, *A. ulmarius*, *A. Cæsarea*, *Boletus edulis*, *B. luridus*, *B. scaber*, *Cantharellus cibarius*, *Clavaria coralloides*, *Fistulina hepatica*, *Helvella crispa*, *H. lacunosa*, *Hydnum repandum*, *Lycoperdon Bovista*, *L. plumbeum*, *Morchella semilibera*, *Peziza acetabula*, *Polyporus corylinus*, *P. frondosus*, *P. tuberaster*, *Verpa digitaliformis*.

Too great caution however cannot be employed in distinguishing the edible from the poisonous species. Iu the markets of Rome au inspector of Funguses is appoiuted, whose duty it is to examine all *Fungi* exposed for sale, and none are allowed to be sold but with his express sanction. But it would appear, from a case quoted in Lindley's 'Vegetable Kingdom,' that *Fungi* which are usually iuocuous may, under certain circumstances, become poisouous. The fungus consumed in this instance by a family in Cambridgeshire was the *Agaricus personatus*, a species sold in Covent Garden under the name of Blewitts, and which all writers agree in regarding as perfectly froo from danger.

The poisonous principles produced in the *Fungi* have sometimes been employed in medicine, an instance of which is given above in the Ergot. The action of a species of *Bovista* has been found similar to that of chloroform. [BOVISTA.] The *Amanita muscaria* possesses an intoxicating property, and is employed by northern nations as an inebriant. The following is the account of Langsdorf, as given by Dr. Greville :—

"This variety of *Amanita muscaria* is used by the inhabitants of the north-eastern parts of Asia iu the same manner as wine, brandy, arrack, opium, &c., is by other nations. Such *Fungi* are found most plentifully about Wischua, Kamtchatka, aud Willowa Derecona, and are very abuudant in some seasons and scarce in others. They are collected in tho hottest months, and hung up hy a string to dry in the air; some dry of themselves on the ground, and are said to be far more narcotic than those artificially preserved. Small deep-coloured specimens thickly covered with warts are also said to be more powerful than those of a larger size and paler colour. The usual mode of taking the fungus is to roll it up like a bolus and swallow it without chewing, which the Kamatchtkadales say would disorder the stomach. It is sometimes eaten fresh in soups and sauces, and then loses much of its intoxicating property. When steeped in the juice of the berries of *Vaccinum uliginosum* its effects are those of a strong wine. One large or two small *Fungi* are a common dose to produce a pleasant intoxication for a whole day, particularly if water be drunk after it, which augments the narcotic principle. The desired effect comes on from one to two hours after taking the fungus. Giddiness and drunkenness result in the same manner as from wine or spirits: cheerful emotions of the mind are first produced, the countenance becomes flushed, involuntary words and actions follow, and sometimes at last an entire loss of consciousness. It renders some remarkably active, and proves highly stimulating to muscular exertion. By too large a dose violent spasmodic effects are produced. So very exciting to the nervous system in many individuals is this fungus that the effects are often very ludicrous. If a person under its influence wishes to step over a straw or a small stick, he takes a stride or a jump sufficient to clear the trunk of a tree. A talkative person cannot keep silence or secrets, and one fond of music is perpetually singing. The most singular effect of the *Amanita* is the influence it possesses over the urine. It is said that from time immemorial the inhabitants have known that the fungus imparts an intoxicating quality to that secretion, which continues for a considerable time after taking it. For instance, a man moderately intoxicated to-day will by the next morning have slept himself sober, but (as is the custom) by taking a tea-cup of his urine he will be more powerfully intoxicated than he was the preceding day. It is therefore not uncommon for confirmed drunkards to preserve their urine as a precious liquor against a scarcity of the fungus. The intoxicating property of the urine is capable of being propagated, for every one who partakes of it has his urine similarly effected. Thus, with a very few *Amanitæ* a party of drunkards may keep up their debauch for a week. Dr. Langsdorf mentions that by means of the second person taking the urine of the first, the third of the second, and so on, the intoxication may be propagated through five individuals."

Fungi are often phosphorescent. The light given out by species of *Rhizomorpha* [RHIZOMORPHA] in the coal-mines of Dresden is described as giving them the appearance of an enchanted castle. *Agaricus Gardneri*, which grows on a sort of palm called Britada in Brazil, is highly luminous. The same phenomenon has been observed in *A. olearius* in the south of Europe, and in two species of *Fungi* at Swan River. Dr. Hooker describes a luminous fungus as growing upon decaying wood in the forests of the Sikkim Himalaya.

It is generally stated that *Fungi* differ from the rest of the vegetable kingdom, in the absorption of oxygen and the disengagement of carbonic acid gas. In experiments which have been performed, this has been the result; but it is well known that the tissues of *Fungi* are easily decomposable, and it is more probable that the absorption of oxygen and the giving out of carbonic acid gas is the result of decay, rather than of the true growth of the plant. The following substances were found by Payen in his analysis of *Fungi*:—1. Water; 2. Cellulose; 3. Three Nitrogenised Substances; 4. Fatty Matters; 5. Sugar; 6. Volatile Matter; 7. Sulphur; 8. Salts, containing Silex and Potash. These substances are analogous to the ordinary products of the decomposition of water, ammonia, and carbonic acid by deoxidation, and must either be formed by that process in the fungus itself, or taken directly up from the substances on which they grow, by absorption.

A curious fact connected with the development of *Fungi* is the occurrence of vegetable cells, referred to this order, in liquids undergoing fermentation. During the conversion of malt into beer, plant-cells are constantly observed to be present, and these have been described as a plant, under the name of *Saccharomyces Cerevisiæ*. During the preparation of flax, as now carried on at Belfast, Professor Allman has observed present cells resembling those of *Saccharomyces*. Whether these are true plant-cells or not, is still a question; and it is still more a question as to whether they have anything to do with the changes going on in the solutions in which they occur. This point is alluded to in the article ENTOPHYTA. They are probably a result, and not the cause, of fermentation. These cells have not escaped the observation of Schleiden, and the following is his account of them:—

"In the last place, I must mention a highly interesting analogy, which, when more accurately examined, may perhaps one day lead to the most satisfactory explanation of the process of cell-formation—I mean vinous fermentation. We have here a fluid in which sugar and dextrin, and a nitrogenous matter, as a cytoblast, are present. At a certain temperature, which is perhaps necessary to the chemical activity of the mucus, there originates, without, as it appears, the influence of a living plant, a process of cell-formation (the origin of the so-called fermentation-fungus), and it appears that it is only the vegetation of these cells which produces the peculiar changes that occur in the fluid. Whether this organism is really a fungus, is a matter of indifference; but whether it alone, through the activity of its vital processes, determines the process of fermentation, deserves to be accurately determined.

"I will here add my own observations on these fermentation-cells. I bruised some currants with sugar, and, having pressed the juice through a cloth, diluted it with water and filtered through folded paper. The fluid was bright red, quite clear and transparent, and, under the microscope, showed no trace of granules, but presented a number of little drops of a pure clear oil. At the end of twenty-four hours the whole fluid was opalescent, and presented, under the microscope, a number of granules suspended in it. On the second day these granules had greatly increased, and there appeared amongst them perfectly-formed ferment-cells. There also appeared, now and then, vesicles of carbonic acid gas. On the fourth day fermentation was very active. At the bottom of the vessel and on the surface of the fluid, yeast had formed; but these yeasts consisted of single cells, or several attached one to another. In the solitary cells could be observed the way in which one cell was formed from another. The ferment-cells do not in this state permit of a distinction between the contents and the membrane of the cell. In the midst of the cell there is a transparent spot; but whether hollow, or a solid nucleus, I could not decide. The remaining parts appeared entirely homogeneous, yellowish like a nitrogenous substance, sometimes mixed with small solitary granules. In a similar way, a solution of sugar with elder-flowers was examined, and gave similar results. Other results were obtained in the following way:—Pure white protein (albumen) from the white of an egg, was dried, and rubbed down with sugar, and left to ferment: the fluid at first was perfectly clear. On the third day, the small portions of protein, which at the commencement exhibited a sharply angular aspect, assumed partly a granular aspect, and some a more or less rounded form. These globules showed an active molecular movement, and some appeared strung together. On the fourth day there was seen between these granules round or elongated cells, which were either solitary, or arranged together in a line with a tendency to the formation of branched fibres. These cells were not more than one-third of the diameter of ordinary ferment-cells. An active fermentation went on, and gas-bubbles were given out from the protein-granules and the linear cells. Proper ferment-cells did not make their appearance. Fluid albumen, mixed with sugar, and filtered, became thickened on the second day, and contained little granules of albumen (coagulated?). The further phenomena were similar to those exhibited by the preceding, except that there were developed a few true ferment-cells. Protein moistened with water displayed the same appearances as when mixed with sugar and water; ultimately putrefaction came on, and the development of *Infusoria*, but the vegetable formation preceded. There appears to be two very different types of ferment-cells, according as the fluid contains organic acids and essential oils or not. From the phenomena exhibited by the ferment-cells, one might be inclined to regard them as similar to animal-cells, which are formed through a cavity in the cytoblast, and which afford indications of the nucleoli in their highest development. But this analogy is not tenable, and the above observations must be regarded as imperfect. If we take fully-developed ferment-cells, and treat them with ether, alcohol, or caustic alkalies, there will be found in the fluid a number of globular delicate cells, with thin but clearly distinguishable walls, which contain a clear fluid, with here and there very small granules, which, alone or in groups, are attached to the inner surface of the cell-wall, and (almost?) always a large round flat body (a cytoblast?)."

The classification of *Fungi* has occupied the attention of many observers. That of Fries is the foundation of most of the systems adopted by modern writers.

Fries in the first place divides the whole order into four Cohorts, distinguished by the following characters:—

Cohort I. HYMENOMYCETES. A Hymenium present; that is, the fungus opened out into a fructifying membrane, in which the spores (seeds) are placed, usually in the inside of asci (transparent simple cases). The texture wholly filamentous.

Cohort II. PYRENOMYCETES. A Perithecium present; that is, the fungus closed up; then perforated by a hole or irregular laceration, and inclosing a distinct kernel holding asci. Texture obscurely cellular; that of the stroma (receptacle) somewhat filamentous.

Cohort. III. GASTEROMYCETES. A Peridium present; that is, the fungus at first closed up, and containing loose spores having no asci. The texture cellular.

Cohort IV. CONIOMYCETES. Spores naked; that is, the fungus in its elementary state, eventually having the spores quite naked, although they may have been covered at first. The texture between filamentous and cellular; and the thallus often apparently absent.

He then subdivides these cohorts each into four Orders, as follows:—

Cohort I.—HYMENOMYCETES.

Order 1. *Pileati.* The Hymenium on the under side, and having asci. (*Fig.* 1, *Agaricus.*)

Order 2 *Elvellacei.* The Hymenium on the upper side, and having asci. (*Fig.* 2, *Morchella.*)

Order 3. *Clavati.* The Hymenium on both sides, and having asci. (*Fig.* 3. *Clavaria.*)

Order 4. *Tremellini.* Amorphous. The Hymenium confounded with the receptacle. Asci none. Membranous or gelatinous, with a filamentous texture. (*Figs.* 4, 5, *Dacrymyces.*)

Hymenomycetous *Fungi.*

1. *Agaricus odorus*, reduced in size; 2, *Morchella esculenta*, reduced in size; 3, *Clavaria cinerea*, reduced in size; 4, *Dacrymyces stillatus*, growing in wood, natural size; 5, the same magnified.

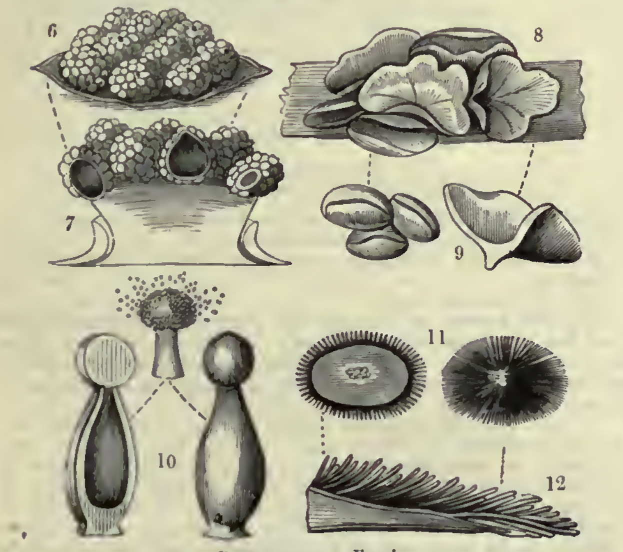
Cohort II.—Pyrenomycetes.

Order 1. *Sphæriacei.* The kernel filled with asci, and deliquescent. (*Figs.* 6, 7, *Cucurbitaria.*)

Order 2. *Phacidiacei.* The kernel filled with asci, and dry. (*Figs*, 8, 9, *Cenangium.*)

Order 3. *Cytisporei.* The kernel filled with naked spore-cases, and disintegrating. (*Fig.* 10, *Sphæronema.*)

Order 4. *Xylomacei.* The kernel filled with naked spore-cases, and dry. (*Figs*, 11, 12, *Actinothyrium.*)



Pyrenomycetous *Fungi.*

6, *Cucurbitaria cinnabarina*, magnified; 7, a section of the same; 8 and 9 *Cenangium ferrugineosum*, magnified; 10, *Sphæronema subulatum*, magnified 11, 12, *Actinothyrium graminis*, magnified.

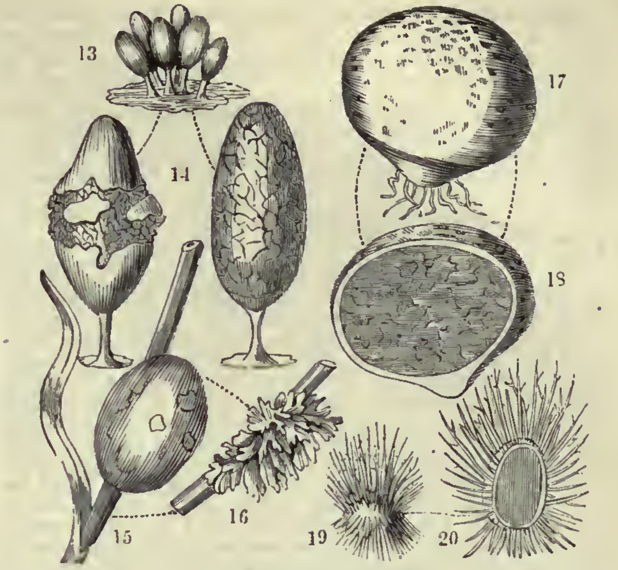
Cohort III.—Gasteromycetes.

Order 1. *Angiogastres.* Spore-cases immersed in a receptacle distinct from the peridium.

Order 2. *Trichospermi.* Spore-cases naked, among filaments distinct from the peridium. (*Figs.* 17, 18, *Scleroderma*; *figs.* 13, 14, *Arcyria.*)

Order 3. *Trichodermacei.* Spore-cases naked, covered by filaments constituting a peridium. (*Figs.* 15, 16, *Spumaria.*)

Order 4. *Sclerotiacei.* Spore-cases immersed in a receptacle constituting the peridium. (*Figs.* 19, 20, *Chætomium.*)



Gasteromycetous *Fungi.*

13 and 14, *Arcyria punicea*, magnified; 15, 16, *Spumaria mucilago*, magnified; 17, 18, *Scleroderma Cepa*, magnified; 19, 20, *Chætomium elatum*, magnified.

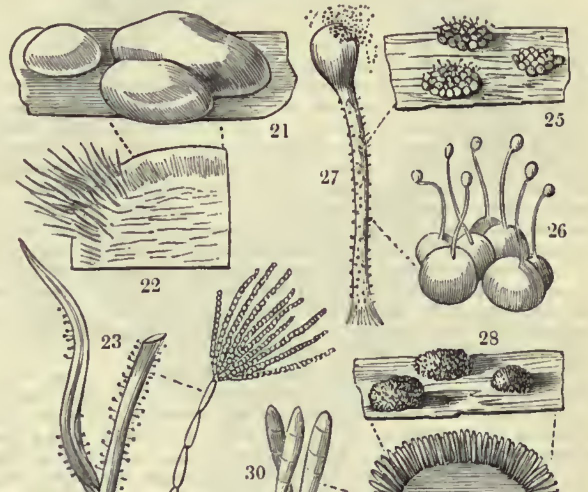
Cohort IV.—Coniomycetes.

Order 1. *Tubercularini.* Spore-cases plunged in an entangled receptacle, upon a free receptacle. (*Figs.* 21, 22, *Fusarium.*)

Order 2. *Mucorini.* Spore-cases upon a filamentous receptacle, at first inclosed in a little peridium. (*Figs.* 25, 26, *Stilbum.*)

Order 3. *Macedines.* Spore-cases at first concealed by filaments. (*Figs.* 23, 24, *Aspergillus.*)

Order 4. *Hypodermi.* Spore-cases springing from under the cuticle of trees. *Figs.* 28, 29, *Exosporium.*)



Coniomycetous *Fungi.*

21, 22, *Fusarium tremelloides*, magnified; 23, a stem of grass covered with *Aspergillus penicillatus*; 24, the fungus itself, magnified; 25, *Stilbum tomentosum*, growing on a piece of wood; 26, a highly magnified representation of the same; 27, a spore case; 28, *Exosporium Tiliæ*, growing on a leaf; 29, a section of the same magnified; 30, three of the spore-cases, still more magnified.

The following arrangement of the *Fungi* is given in Lindley's 'Vegetable Kingdom':—

Spores generally quaternate, on distinct Sporophores. Hymenium naked.	*Hymenomycetes*, or *Agaricaceæ*.
Spores generally quaternate, on distinct Sphorophores. Hymenium inclosed in a Peridium. .	*Gasteromycetes*, or *Lycoperdaceæ*.
Spores single, often septate, on more or less distinct Sporophores. Flocci of the fruit obsolete, or mere poduncles.	*Coniomycetes*, or *Uredinaceæ*.
Spores naked, often septate. Thallus floccose.	*Hyphomycetes*, or *Bothylaceæ*.

Sporidia contained (generally eight together) in Asci. } *Ascomycetes*, or *Helvellaceæ*.

Spores surrounded by a vesicular veil or Sporangium. Thallus floccose. } *Physomycetes*, or *Mucoraceæ*.

(Fries, *Systema Mycologicum*; Greville, *Cryptogamic Flora*; *Neues System der Pilze*; Corda, *Icones*; Endlicher, *Genera Plantarum*; Hooker, *British Flora*; Sowerby, *Fungi*; Bulliard, *Figures of Fungi*; Lindley, *Vegetable Kingdom*; Berkeley, *Papers in Annals of Natural History*.)

FUNGIA. [MADREPHYLLIÆA.]

FURNARIUS. [CERTHIADÆ.]

FURZE. [ULEX.]

FUSTIC. This name appears to be derived from Fustet, the French name of a yellow dye-wood, the produce of Venetian sumach. A wood similar in colour and uses, but larger in size, having been subsequently imported from the New World, had the same name applied to it with the addition of Old, while the other, being smaller, is called Young Fustic; but these, so far from being the produce of the same tree at different ages, do not even belong to the same genus.

Young Fustic, or as it is sometimes called Zante Fustic, is the produce of *Rhus Cotinus* (*Anacardiaceæ*), a native of Italy, the south of France, and of Greece; much of it is exported from Patras in the Morea; and it also extends into Asia. It is supposed to be the *Cotinus* of Pliny, being still called Scotino near Valcimara, in the Apennines, where it is cultivated on account of its uses in tanning. The root and the wood of this shrub are both imported, deprived of their bark, and employed for dyeing a yellow colour approaching to orange, upon wool or cottons, prepared either with alum or the nitromuriate of tin with the addition of tartar. The colour is a beautiful bright yellow, and permanent when proper mordants are employed. Only small quantities of this kind of Fustic are imported.

Dr. Sibthorp was of opinion that *Rhamnus infectoria*, or *R. oleoides*, of which the berries are called French and Persian Berries, yielded the Fustic of commerce, and informs us that its yellow wood is called by the Greeks 'chrysoxylon.' He also thought that it was the *Lycium* of Dioscorides, but this has been shown by Dr. Royle to be a species of *Berberis*, of which genus all the species have yellow wood.

Old Fustic, the 'Bois Jaune' of the French, is on the contrary the produce of a large tree, *Morus tinctoria*, the Dyer's Mulberry, of the natural family of *Urticaceæ*, a native of Tropical America and the West India Islands. The tree attains a height of 60 feet; the wood is yellow-coloured, hard, and strong, but easily splintered, and is imported in the form of large logs or blocks. The yellow colour which it affords with an aluminous base, though durable, is not very bright. M. Chaptal discovered that glue, by precipitating its tannin, enabled its decoctions to die yellow almost as bright as those of weld and quercitron bark. The Fustic from Cuba is preferred, and fetches the highest price, varying from 8*l.* to 9*l.* 10*s.*, while that from Jamaica or Columbia varies from 5*l.* 10*s.* to 6*l.* 10*s.* per ton. The tree is figured by Sloane, and noticed by Marcgrave and Piso. Browne describes it as a native of Jamaica, and deserving the attention of planters, as it is only propagated by birds, who are fond of its sweet roundish fruit.

The several countries from which Fustic was imported, and the respective quantities received from each, were in 1836—

	Tons.
Italy and the Italian Islands	4
Ionian Islands	72
Morea and Greek Islands	18
British North American colonies	103
British West Indies	2053
United States of America	226
Mexico	172
Columbia	1913
Brazil	356
Total	4917

In 1850 the quantity imported into Liverpool was 9808 tons, of this 1771 tons were re-exported.

(Simmonds, *The Commercial Products of the Vegetable Kingdom*.)

FUSUS. [SIPHONOSTOMATA.]

G

GAD-FLY. [BOTS; ŒSTRIDÆ.]

GADIDÆ, a family of Fishes, generally arranged as the first of the sub-brachiate division of the *Malacopterygii*. This family embraces the whole of the species of the Linnæan genus *Gadus*. They are easily known by the position of the ventral fins under the throat, and the pointed character of these fins. The body is rather long, a little compressed, and covered with small soft scales. The head is well-proportioned and naked. All their fins are soft. The jaws and front of the vomer have unequal pointed teeth of middle or small size, and disposed in several rows like a card or rasp. The gill-covers are large, and they have seven rays. Most of the species have the dorsal fin contained in two or three bundles; they have also fins behind the vent, and a distinct caudal fin. The stomach is large, and the intestine long. The air-bladder is large and strong, and in some cases notched on the margins.

The greater number of the species of *Gadidæ* live in the cold or temperate seas, and furnish the greater portion of the fish obtained in the fisheries of Europe and America. The flesh of most of the species is white, easily separable into flakes, is agreeable to the taste, and easy of digestion. They are probably more useful to man than any other family of fishes. Their reproductive powers are very great, and the numbers in which they exist in some parts of the ocean is perfectly incalculable.

A detailed account of these fish is given under their generic names. The following are the British species of this genus as given in the 'British Museum Catalogue':—

I. *Morrhua*. [MORRHUA.]

1. *Morrhua Callarias*, Common Cod.
2. *M. Æglefinus*, Haddock.
3. *M. lusca*, Bib and Pout.
4. *M. minuta*, Poor.

II. *Merlangus*. [MERLANGUS.]

1. *Merlangus vulgaris*, Whiting.
2. *M. albus*, Couch's Whiting.
3. *M. carbonarius*, Coal-Fish.
4. *M. Pollachius*, Pollack.

III. *Merlucius*. [MERLUCIUS.]

1. *Merlucius vulgaris*, Common Hake.

IV. *Lota*. [LOTA.]

1. *Lota molva*, Ling.
2. *L. vulgaris*, Burbot.

V. *Motella*. [MOTELLA.]

1. *Motella tricirrata*, Three-Bearded Rock-Ling.
2. *M. cimbria*, Four-Bearded Rock-Ling.
3. *M. mustela*, Five-Bearded Rock-Ling.
4. *M. argenteola*, Silvery Gade.

VI. *Brosmius*. [BROSMIUS.]

1. *Brosmius Brosme*, Torsk.

VII. *Phycis*. [PHYCIS.]

1. *Phycis bifurcus*, Forked Hake.

VIII. *Raniceps*. [RANICEPS.]

1. *Raniceps fuscus*, Trifurcated Hake.

The genus *Brotula* is found in the West Indian Seas, and *Lepidoleprus* in the Mediterranean and Atlantic Seas.

GADOLINITE, a Mineral, containing Yttrium. [PYROCHLORE; YTTRIUM.]

GADWALL. [DUCKS.]

GA'GEA, a genus of Plants belonging to the natural order *Liliaceæ*, and the tribe *Asphodeleæ*. It has a perianth of six patent leaves, the stamen adhering to the base of the perianth; the anthers erect, attached by their bases. The flowers of the species are corymbose or umbellate.

G. lutea (the *Ornithogalum luteum* of many botanists) has the radical leaves usually solitary, linear-lanceolate, flat; the bracts two, opposite; the peduncles umbellate, simple, glabrous; the segments of the perianth oblong, obtuse; the bulb ovate, solitary. The stem of this plant is about 6 inches high, and shorter than the leaves. Its flowers are yellow. It is a native of England and Scotland in woods, but is a rare plant. It is a native of Europe, and is found on the Alps in Switzerland. Koch describes 10 species of this genus as natives of Germany and Switzerland.

(Babington, *Manual of British Botany*; Koch, *Flora Germanica*.)

GAHNITE, a Mineral, also called *Automolite*. It is a variety of *Spinel*, containing 34·8 per cent. of oxide of zinc. It has a dark green or black colour. Its hardness is 7·5 to 8, and specific gravity 4·26. It is infusible alone, and nearly so with borax. With soda it forms at first a dark scoria, and when fused again with more soda, a ring of oxide of zinc on the charcoal.

GALAGO. [LEMURIDÆ.]

GALANGA, or GALANGAL, is usually supposed to have been introduced by the Arabs, but it was previously mentioned by Ætius. The Arabs call it Khelingan, which appears to be derived from the Hindoo Koolinjan, or Sanscrit Koolunjuna, indicating the country whence they derived the root, as well as the people from whom they obtained their information respecting its uses. The plant which yielded this root was long unknown, and it was supposed to be that of a Pepper, of an Iris, of *Acorus Calamus*, or to be the *Acorus* of the ancients. *Kæmpferia Galanga* was so called from its aromatic roots being supposed to be the true *Galangal*. The tubers of *Cyperus longus* were sometimes substituted, and called English Galangal. Two kinds, the large and the small galangal, are described; these are usually considered to be derived from the same plant at different stages of its growth, but Dr. Ainslie, in his 'Materia Indica,' insists upon the greater value of the lesser, as this is warmer and more fragrant, and therefore highly prized in India. It is a native of China, and the plant producing it is unknown. Dr. Ainslie does not prove that it is the *Galanga minor* of Europe.

The Greater Galangal has long been known to be the produce of a Scitamineous plant, the *Galanga major* of Rumphius ('Herb. Amb.' 5. t. 63), which is the *Alpinia Galanga* of Wildenow, and a native of China and the Malayan Archipelago. It is fully described by Dr. Roxburgh, in his 'Flora Indica,' vol. i. p. 28, ed. Wall. The roots, perennial and tuberous, like those of the ginger, were ascertained by Sir Joseph Banks and Dr. Comb to be identical with the *Galanga major* of the shops. This is cylindrical, often forked, thick as the thumb, reddish-brown externally, marked with whitish circular rings, internally lighter coloured, of an agreeable aromatic smell, and a hot spicy taste, like a mixture of pepper and ginger, with some bitterness. The stem is perennial, or at least more durable than those of herbaceous plants. When in flower, about 6 or 7 feet in length; its lower half invested by leafless sheaths. The leaves are two-ranked, lanceolar, from 12 to 24 inches long, and from 4 to 6 inches broad. Panicle terminal, crowned with numerous branches, each supporting from two to five pale greenish-white and somewhat fragrant flowers in April and May in Calcutta, where the seeds ripen, though rarely, in November.

Several species of this genus have roots with somewhat similar properties. Thus *Alpinia alba* and *A. Chinensis* are much used by the Malays and Chinese; the former has hence been called *Galanga alba* of Kœnig; and the latter has an aromatic root with an acrid burning flavour. The fragrant root of *Alpinia nutans* is sometimes brought to England, according to Dr. Roxburgh, for *Galanga major*. Its leaves, when bruised, have a strong smell of cardamoms, and the *Cardamomum* plant is frequently placed in this genus, but has been described under ELETTARIA.

GALANTHUS, a genus of Plants belonging to the natural order *Amaryllidaceæ*, consisting of the Snowdrop and another species. The former plant is a native of subalpine woods in various parts of Europe; the second, which is the *G. plicatus* of botanists, inhabits the Asiatic provinces of the Russian and Turkish empires.

Galanthus is thus characterised:—Perianth 6-parted, 3 outer segments spreading, 3 inner shorter, erect, emarginate. Stamens equal, subulate.

G. nivalis, the Snowdrop, has white drooping flowers with the inner segments greenish. The scape 1-flowered, the leaves 2, keeled, broadly linear, glaucous. It grows in thickets, and blossoms in February and March.

GALATHEA. [GALATHEIDÆ.]

GALATHEIDÆ, a group of Crustaceans corresponding with the genus *Galathea* of Fabricius, and establishing, in the opinion of M. Milne-Edwards, a passage between the Anomurous and Macrurous Crustaceans, being more particularly approximated to the *Porcellanæ*. [PORCELLANIDÆ.] Dr. Leach divided the genus established by Fabricius into four: namely, the true *Galatheæ*, *Munidea*, *Grimothea*, and *Æglea*. M. Milne-Edwards thinks that three of these genera should be preserved, but agrees with M. Desmarest in coming to the conclusion that the genus *Munidea* has not sufficient characteristics to admit of its adoption in a natural classification. With regard to *Æglea*, M. Milne-Edwards considers it as approximating more to the *Porcellanæ* than to the *Galatheæ*, and as occupying a place in the section of the *Anomura*.

The *Galatheidæ*, then, according to the revision of M. Milne-Edwards, are thus distinguished:—Carapace depressed and wide, but still longer than its width, terminating anteriorly by a rostrum more or less projecting, which covers the place of the ocular peduncles, and presents on its upper surface many furrows or wrinkles, among which one deeper than the rest defines the posterior part of the stomachic region. Antennæ inserted on the same transversal line; internal antennæ but little elongated, placed under the ocular peduncles, and terminated by two small, multiarticulate, very short filaments; external antennæ with no trace of palpiform appendages at their base, but with a cylindrical peduncle and a long and slender terminal filament. External jaw-feet (pates-mâchoires) always pediform, but varying a little in their conformation. Sternal plate (plastron sternal) widening a good deal posteriorly, and the last thoracic ring ordinarily distinct. Anterior feet large, and terminated by a well-formed claw; those of the three following pairs of limbs rather stout, and terminated by a conical tarsus; fifth pair very slender, and folded above the others in the branchial cavity; these last do not assist the locomotion, and are terminated by a rudimentary hand. Abdomen nearly as wide as the thorax, and longer, vaulted above and armed on each side with a row of four or five large teeth formed by the lateral angle of the superior arch of the different rings composing it, and terminated, as in the greater part of the Macrurous Crustaceans, with a large fan-shaped lamelliform fin. The number of abdominal false feet varies; in the male there are five pairs, the first two of which are slender and elongated, and the last three are terminated by an oval lamina ciliated on the edge; in the female, the first abdominal ring is without appendages, but the four following segments have each a pair of false feet composed of three joints placed end to end, and fringed with hairs for the attachment of the eggs.

Galathea.—The whole surface of the carapace covered with transverse furrows fringed with small brush-like hairs. Hepatic regions, in general, well distinguished from the branchial, and occupying with the stomachic region nearly half of the space of the carapace. Rostrum projecting and spiny; eyes large and directed downwards; no trace of an orbit. A spine above the insertion of the external antennæ, and two others on the anterior part of the stomachic region. Basilary joint of the internal antennæ cylindrical and armed at its anterior extremity with many strong spines; the two following joints slender and nearly as long as the first. Peduncle of the external antennæ composed of three small cylindrical joints, the last of which is much smaller than the others. External jaw-feet moderate, the two last joints neither foliaceous nor even enlarged. Anterior feet long and depressed. (Milne-Edwards.)

*

Species whose external jaw-feet present a row of teeth on the internal edge of their second joint.

a Third joint of the external jaw-feet shorter than the second.

G. strigosa (*G. spingera*, Leach; *Cancer strigosus*, Linn.). It has the rostrum triangular and armed with seven strong projecting spiniform teeth. Lateral edges of the carapace with strong spiniform teeth. Three long spines at the anterior extremity of the first joint

Galathea strigosa.

of the external antennæ; a great spine under the auditory tubercle, two smaller ones on the first joint of the external antennæ, and one on their second joint. External jaw-feet short, hardly overpassing the rostrum when they are extended, their third joint much shorter than the second, and armed beneath with two strong spines. Anterior feet long, depressed, and very spiny; the hand very large, edged with spines and ornamented above with small piliferous furrows resembling imbricated scales; claws short, large, and with a spoon-shaped termination. Feet of the second and third pair of the same length. Abdomen furrowed transversely, but without a spine; the seventh segment a little widened and rather narrower behind than before. Colour reddish, with some blue lines on the carapace. Length about five inches. It is found in the Mediterranean, and is not uncommon on the coasts of Great Britain. Mr. Couch says it is common on the whole of the south coast of Cornwall. It frequents pools between tide-marks where there are loose stones and sand.

β. Third joint of the external jaw-feet much longer than the second.

G. squamifera. It is found on the coasts of England and France.

**

Species whose external jaw-feet have no dentilation on the internal edge of their second joint.

G. Monodon. It inhabits the coasts of Chili.

G. nexa, a new species described by Dr. Embleton, is found on the English and Irish coasts.

Grimothea.—Differing but little from *Galathea*, and hardly sufficiently distinct for separation. General form of both essentially the same, but the basilary joint of their internal antennæ is claviform and hardly dentated at its extremity, and the external jaw-feet are very long, and have their three last joints enlarged and foliaceous. (Milne-Edwards).

M. Milne-Edwards observes that the crustacean figured by M. Guérin under the name of Grimothée Sociale ('Voyage of La Coquille:' Crust., pl. 3, fig. 1) differs from *G. gregaria* in the form of the caudal fin, the middle lamina of which is less than the lateral ones. M. Edwards proposes therefore to name it *Grimothea Duperreii*, in honour of the navigator whose voyage made the species known.

GALAXAURA. [PSEUDOZOARIA.]

GALBA. [ELATERIDÆ.]

GA'LBANUM. Though the drug known by this name is one of those which have been the longest known, the plant which yields it still remains undetermined, though it is stated by old writers to be a native of Syria. The Greek name Chálbane (χαλβάνη) is evidently the same as the Hebrew Chelbenah, by which the same substance is supposed to be alluded to in the book of Exodus. Arabian authors describe it under the name Barzud. The Persians call it Birzud, and give Birceja as its Hindoo synonym. That the same substance is intended, is evident from Khulyan and Metonyon, as stated by Dr. Royle ('Illustr. Himal. Bot.,' p. 23), being given as its Greek synonyms, which are evident corruptions of Chalbane and Metopion, the names of this substance in Dioscorides. The plant yielding this substance is called Kinneh and Nafeel by Arabian and Persian authors, by whom it is described as being jointed, thorny, and fragrant. Under the first name it is noticed in the original of Avicenna, but omitted in the Latin translation. D'Herbelot ('Bibl. Orient.') however states, that the plant yielding Galbanum is called Ghiarkust in Persia. These names are interesting only as showing that both the plant and gum-resin appear to have been familiarly known to both Arabians and Persians, and that therefore the former is probably a native of these countries, though usually stated to be only a native of Syria. But if so, it could hardly have escaped the notice of the numerous travellers who have visited that country.

One plant, often described as yielding this long-known gum-resin, is *Bubon Galbanum*, a native of the Cape of Good Hope, which Hermann describes as yielding spontaneously, by incision, a gummy, resinous juice, similar to Galbanum; but Mr. Don has observed that this plant possesses neither the smell nor the taste of Galbanum, but in these particulars agrees better with fennel; and its fruit has no resemblance whatever to that found in the gum. The fruit, commonly called seed, was early ascertained by Lobel to be that of an Umbelliferous Plant, broad and foliaceous, which he picked out of *Galbanum*, and, having sowed, obtained a plant, which he has figured under the name of *Ferula galbanifera*. This has been lost or become confounded with other species; but it is probable that it was the plant yielding Galbanum, as Mr. Don has recently obtained fruit in like manner, and something similar, which he has determined to be allied to the genus *Siler*, but differing in the absence of dorsal resiniferous canals, and the commissure being furnished with only two. The carpels are about 9 lines in length and 4 lines broad, flat internally and somewhat converse externally. As the plant is still unknown, it is well worthy the investigation of travellers in the East, who might otherwise suppose, from the name, assigned from the seed, having been adopted in the 'London Pharmacopœia,' that the plant was as well known as its product.

Three sorts of Galbanum are distinguished:—1. Galbanum in grains or tears; 2. Galbanum in masses; and 3. Persian Galbanum. The two former come from Africa, especially Æthiopia; the third sort from Persia. Galbanum in tears is most likely the spontaneous exudation from the plant; and that in masses, obtained by incisions. The first sort occurs in irregular generally oblong grains, mostly distinct, but sometimes agglutinated together, about the size of a lentil or small pea, of a colour verging from whitish into yellowish-brown, more or less diaphanous, opaque, or shining with a resinous lustre. The odour is strongly balsamic, and disagreeable. The taste is resinous, sharp, bitter, and disagreeable. Specific gravity, 1·212.

It is partially soluble in alcohol, and the solution, as well as the strong white smoke which is evolved when Galbanum is melted in a platinum spoon, reddens litmus paper. It consists chiefly of resin, gum, volatile oil, and a trace of malic acid.

Galbanum in masses consists of irregular pieces of a yellowish or dark brown colour; the odour is stronger than that of the preceding kind, which, in its general characters, it much resembles, except that it can be powdered only during the low temperature of winter. Geiger says that when this variety is pure, it is not to be reckoned inferior to the former. Persian Galbanum, being very soft and tenacious, is sent in skins or chests. It often contains many fragments of plants.

Galbanum, like other umbelliferous gum-resins, is anti-spasmodic, expectorant, and externally rubefacient. It is inferior in power to assafœtida, but usually associated with it in pills and plasters.

GALBULA. [HALCYONIDÆ.]

GALE, SWEET. [MYRICA.]

GALENA. [LEAD.]

GALEOLARIA. [ACALEPHÆ.]

GALEOPITHECUS, a genus of *Mammalia*, having relations to the *Lemuridæ* and *Cheiroptera*. It is often formed into a family, and is then called *Pleuroptera* or *Galeopithecidæ*. They are commonly known by the name of Flying Lemurs, and are sometimes called Flying Cats and Flying Foxes. They are generally arranged under the order Carnassiers, and some authors place them in the division *Cheiroptera*; but they differ from the Bats inasmuch as the toes of their anterior extremities, which are all furnished with sharp claws, are not more elongated than those of the hind feet, so that the membrane which occupies the interval between the extremities to the sides of the tail can hardly operate in executing more than the functions of a parachute. The dental formula is as follows:—

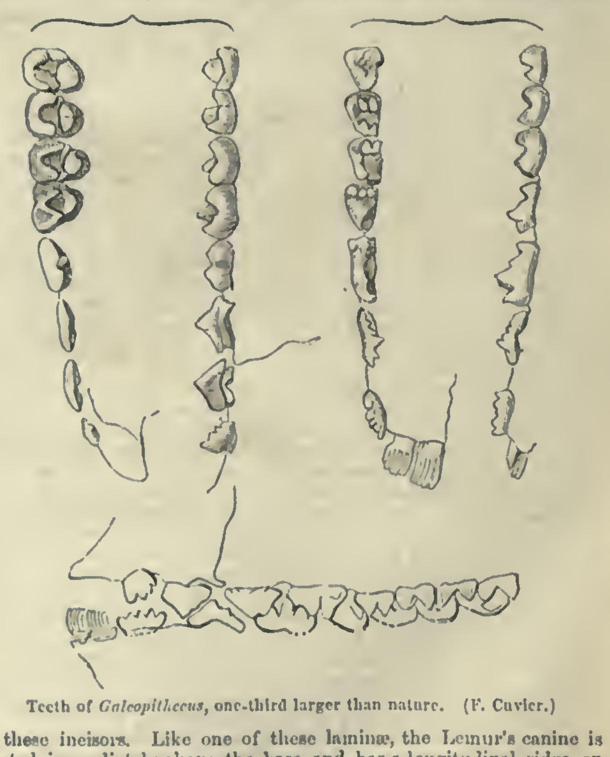
$$\text{Incisors, } \frac{4}{6}\text{; Canines, } \frac{0-0}{0-0}\text{; Molars, } \frac{6-6}{6-6} = 34.$$

This is the formula given by M. Lesson; but Cuvier, in his 'Règne Animal,' states that the canines are dentilated and short like the molars. He states that the two upper incisors are also dentilated and much separated from each other; and that the six lower ones are split into narrow strips like combs, a structure peculiar to this genus.

F. Cuvier's formula is similar to that of M. Lesson, and was probably copied by the latter. F. Cuvier describes the 12 molars in both jaws as consisting of 4 false molars and 8 molars. He tells us that in the upper jaw, the intermaxillary bone, though very extensive, has no teeth in its anterior part; in the posterior part there are two on each side. The descending line in the upper part of the lower figure marks the extent of the intermaxillary bone. The dentition, as it appears to Mr. Waterhouse, is as follows:—

$$\text{Incisors, } \frac{2-2}{4}\text{; Canines, } \frac{0-0}{1-1}\text{; False Molars, } \frac{2-2}{2-2}\text{; True Molars } \frac{4-4}{4-4} = 34.$$

The same author observes that the six foremost teeth in the lower jaw of the Lemur (four only of which are, in his opinion, incisors; for he agrees with Geoffroy in considering the remaining two as canines) together bear a remarkable resemblance to a single incisor of *Galeopithecus*. He compares the two canines to the outer laminæ of one



Teeth of *Galeopithecus*, one-third larger than nature. (F. Cuvier.)

of these incisors. Like one of these laminæ, the Lemur's canine is dilated immediately above the base, and has a longitudinal ridge on the upper side; whilst the incisors, like the intermediate laminæ, are grooved on the outer side near the apex. In their almost horizontal direction there is also a resemblance. In the number of teeth the *Galeopitheci* agree with the Lemurs, excepting that in the former the upper canines are wanting. In both these groups of animals the incisors of the lower jaw are, he observes, opposed to a toothless portion of the intermaxillaries. ('Zool. Trans.,' vol. ii. part 4.)

Cuvier and others state that the *Galeopitheci* live on trees in the islands of the Indian Archipelago, and there pursue insects, and perhaps birds, as their prey: judging from the detrition of the teeth with age, he thinks that they must also feed on fruits. They have a very large cæcum. In their teeth they present many analogies to the *Lemuridæ*.

Dr. Gray makes the *Galeopithecidæ* the fourth family of the (quadrupedoid) *Primates*, and places it between the *Lemuridæ* and *Vespertilionidæ*. ('Outline,' &c., in 'Ann. of Philosophy,' 1825.)

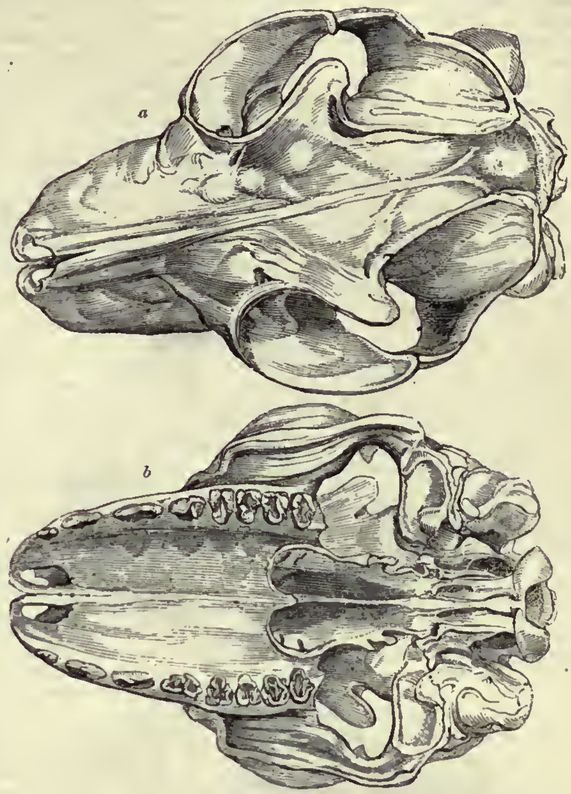
Speaking of the *Galeopithecus* of Pallas, Mr. Swainson observes:—"To give its most striking character in a few words, it is a lemur, with the limbs connected with a bat-like membrane, or, in other words, surrounded by a thin skin which they support, as the framework of an umbrella supports its covering. By this singular structure the animal is supported in the air; yet without the power, like the bats, of sustaining a continued flight. Linnæus places this remarkable genus with the lemurs, while every one must perceive its intimate affinity to the bats; like them, also, these bat-lemurs are nocturnal and insectivorous. The mammæ are pectoral; and they sleep suspended by their hind legs with their heads downward. M. Geoffroy St. Hilaire therefore justly considers them as the form by which the lemurs and bats are connected; while their greater resemblance to the former induces us to consider *Galeopithecus* as one of the aberrant types of the *Lemuridæ*," among which Mr. Swainson arranges the genus, in the third part of his volume, between *Aötes* and *Cheirogaleus*. ('Natural History and Classification of Quadrupeds,' 1835.)

Three species have been recorded:—1. *Galeopithecus rufus*, Geoff., Audubon (*Lemur volans*, Linn.); 2. *Galeopithecus variegatus*, Cuv., Geoff.; 3. *Galeopithecus Ternatensis*, Geoff.: but the general opinion seems to have been that one only, the *Lemur volans* of Linnæus, had been satisfactorily made out. In October, 1838, some specimens of Flying Lemurs were upon the table at a meeting of the Zoological Society of London; and in reference to them Mr. Waterhouse pointed out certain characters which appeared to him to indicate the existence of two species in those specimens.

He remarked that in systematic works three species of the genus *Galeopithecus* are described, founded upon differences of size and colour. As regards the latter character, he had never seen two specimens which precisely agreed; and with respect to size, the dimensions given of two out of the three species are, he observed, evidently taken from extremely young animals. Mr. Waterhouse then proceeded to distinguish the two species on the table, and proposed for them the specific names of *Temminckii* and *Philippinensis*.

Galeopithecus Temminckii.

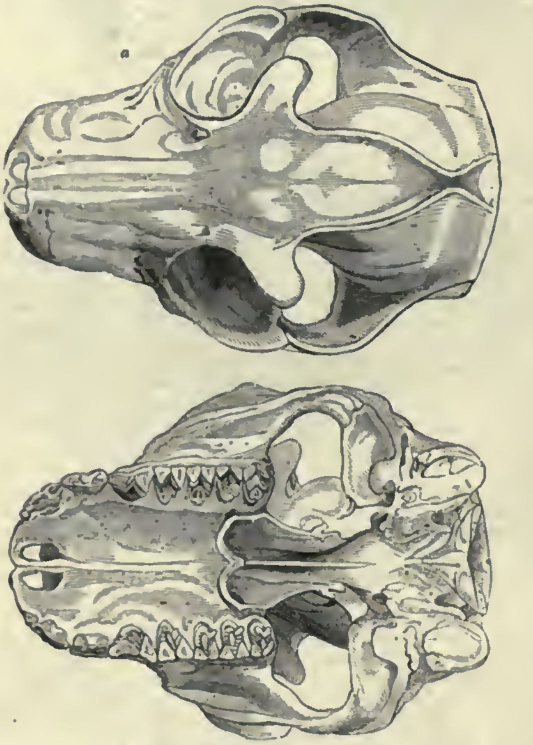
The first and larger species measured about two feet in total length, and its skull was 2 inches 11½ lines in length. The anterior incisor of the upper jaw is broad, and divided by two notches into three distinct lobes; the next incisor on each side has its anterior and posterior margins notched; and the first molar (or the tooth which occupies the situation of the canine) has its posterior edge distinctly notched. This tooth is separated by a narrow space, anteriorly and posteriorly, from the second incisor in front and the second molar behind; the temporal ridges converge towards the occiput, near which however, he observed, they are separated usually by a space of about four lines. This is probably the *Galeopithecus volans* of authors; but the identity cannot be said to be certain.



Skull of *Galeopithecus Temminckii.*
a, seen from above; *b*, seen from below. (Waterhouse, 'Zool. Trans.')

Lower Jaw and Teeth of *Galeopithecus Temminckii.*
1, under side of the Lower Jaw; 2, side view of the same; 3, the three foremost teeth on either side of the Upper Jaw; 4, 5, outer and inner incisors of the Lower Jaw. (Waterhouse, 'Zool. Trans.')

The second species, *G. Philippinensis*, was described by Mr. Waterhouse as being usually about 20 inches in length, and its skull as measuring 2 inches 7 lines in length. He observed that this species may be distinguished from *G. Temminckii* by the proportionately larger ears and the greater length of the hands. The skull too he described as narrower in proportion to its length, the muzzle as broader and more obtuse, and the orbit as smaller. The temporal ridges, he observed, generally meet near the occiput, or are separated by a very narrow space. The anterior incisor of the upper jaw is narrow, and has but one notch; the next incisor on each side is considerably larger, longer, and stronger than in *G. Temminckii*, and differs moreover in having its edges even: the same remark applies to the first false molar. In this species the incisors and molars form a continuous series, each tooth being in contact with that which precedes and that which is behind it. But Mr. Waterhouse concluded by observing that the most important difference perhaps which exists between the two species in question consists in the much larger size of the molar teeth in the smaller skull, the five posterior molars occupying a space of ten lines in length, whereas in *G. Temminckii*, a much larger animal, the same teeth only occupy nine lines. Several minor points of distinction existed besides those here mentioned. ('Zool. Proc.,' 1839; and see further 'Zool. Trans.,' vol. ii. p. 335.)



Skull of *Galeopithecus Philippinensis*.
a, upper side; *b*, under side.

Lower Jaw and Teeth of *Galeopithecus Philippinensis*.
1, under side of the Lower Jaw; 2, side view of the same; 3, the three foremost teeth, Upper Jaw; 4, 5, outer and inner incisors of Lower Jaw. (Waterhouse, 'Zool. Trans.')

Mr. Waterhouse remarks that the first two of the three foremost teeth of the upper jaw, commencing with the smallest tooth, are situated in the intermaxillary bone, and are therefore incisors. He adds that it is worthy of observation, that the posterior of these two teeth (on each side) has a double fang.

GALEOPSIS (from γαλῆ, a weasel, and ὄψις, sight, aspect, the mouth of the corolla gaping like that of a weasel), a genus of Plants belonging to the natural order *Labiatæ* or *Lamiaceæ*. It has the anthers approaching in pairs, opposite cells bursting by two valves transversely; the upper lip of the corolla arched, and the lower lip 3-lobed, unequal, with two teeth on its upper side; a tubular 5-toothed calyx, with equal teeth, or the two upper ones longest. The nuts are rounded at the end. The species of this genus are annual divaricately branched erect herbs, and rarely decumbent at the base. The flowers are red or cream-coloured, or varied with both these colours. This genus may be easily recognised by the peculiar formation of its anthers, which differs from any other of the *Labiatæ*.

G. ochroleuca, the Cream-coloured Hemp-Nettle, has a softly pubescent stem with deflexed hairs, not thickened below the joints, oblong or oblong-lanceolate leaves, clothed with soft villi on both surfaces. The calyx is shaggy and glandular, and the upper lip of the corolla deeply cut. This species is found in the sandy corn-fields of middle Europe, and also in England and Wales. The flowers are of a pale-yellow or cream-colour, and bloom during the months of July and August.

G. ladanum, the Red Hemp-Nettle, is distinguished by having the upper lip of the corolla slightly notched. It is a native throughout Europe, and is found plentifully in the sandy corn-fields of Great Britain. The flowers are of a purple colour, variegated with crimson and white. A variety of this species, with flowers half the usual size, is the *G. intermedia* of Reichenbach, and the *G. parviflora* of Lambert.

G. tetrahit, the Common Hemp-Nettle, has a hispid stem, thickened below the joints, with oblong, ovate, acuminate, serrate leaves. The calyx has tubular teeth, and a tube nearly equal. The tube of the corolla is as long as the calyx, and has an ovate upper lip. It is of a purple colour, and is a native of cultivated ground throughout Europe and Middle Asia, and is plentiful in Great Britain.

G. versicolor has the tube of the corolla much longer than the calyx. The flowers are very large, yellow, and have a broad purple spot on the lower lip. It is not easily distinguished by description from *G. tetrahit*, of which it is regarded as a variety by many botanists.

(Don, *Dichlamydeous Plants*; Babington, *Manual of British Botany*.)

GALERITES. [CONULUS; ECHINIDÆ.]

GALEUS. [SQUALIDÆ.]

GALIA'CEÆ, *Stellates*, a natural order of Exogenous Plants called *Stellatæ* by Linnæus, and merged in *Cinchonaceæ* by the school of Jussieu. It consists of herbaceous usually square-stemmed plants, with a scabrous surface, verticillate leaves, and monopetalous flowers, with an inferior didymous fruit inclosing a couple of seeds containing an embryo lying in a great quantity of horny albumen. Some yield a dyeing substance in their roots, as the various species of Madder, but the greater part are useless weeds. One of our common British species of *Galium*, namely, *G. verum*, is astringent, and was formerly used by farmers to curdle milk.

1, *Sherardia arvensis*; 2, a perfect flower, magnified; 3, a vertical section of the same, without the corolla; 4, a transverse section of a ripe fruit.

The species are natives of the northern parts of the northern hemisphere, where they are very common weeds. The order is related to *Cinchonaceæ*, *Cornaceæ*, and *Apiaceæ*. There are 8 genera and 320 species. [GALIUM; MADDER; ASPERULA.]

GALIPE'A, a genus of Plants belonging to the natural order *Rutaceæ*, inhabiting the warmer parts of South America. Their leaves are often simple, occasionally 3-4-5-leafleted, not divided at the edge, covered with pellucid or grandular dots. The flowers are small, white or pink, often fragrant, in axillary, extra-axillary or terminal racemes, corymbs, or panicles.

G. cusparia is a tree from 60 to 80 feet high, evergreen, with an ash-coloured bark and a pale yellow box-like wood. The leaves are alternate, long-stalked; the leaflets 3, sessile, unequal, ovate, lanceolate, acute, smooth, entire, bright-green, gratefully fragrant, with scattered glandular dots. The flowers are in axillary and terminal racemes, on a peduncle as long as the petioles. The calyx and corolla are white, with fascicles of hairs seated on glandular bodies on the outside. The anthers have two short appendages. This species is said by Humboldt to produce Angostura Bark, but this is denied by Dr. Hancock, who assigns it to the following species.

G. officinalis is found in the higher lands of the missions of Carowy. It is well known in the southern and back missions of the Orinoco. The bark is smooth. The leaves alternate, 3-foliate; the petiole about the length of the leaflets, slightly channelled, the leaflets ovate, acute at the base, acuminate at the apex, smooth, glossy, bright-green, smelling when bruised and fresh like tobacco; from 6 to 10 inches long, 2 to 4 inches broad; some of the leaflets are marked with small whitish round spots. The panicles are cylindrical, contracted, stalked, longer than the leaves, with the branches about 3-flowered. The calyx is campanulate, 5-toothed, hairy. The corolla white, somewhat curved before expansion; nearly an inch long, downy on both sides; of the 5 petals two larger than the others. There are 5 sterile stamens, tipped with a pellucid watery gland. The fertile stamens 2 in number, 5 carpels or fewer, becoming villous as they mature; 2-seeded, with a strong elastic separable 2-valved endocarp. According to Dr. Hancock, this, which he found to yield the true Angostura, or Carowy Bark, is essentially different from the *Cusparia febrifuga* of Humboldt. An excellent account of that bark is given by Dr. Hancock in the 'Transactions of the Medico-Botanical Society.' "I am fully convinced," says he, "from ample experience of the virtues of this bark, that it is one of the most valuable febrifuges we possess, being adapted to the worst and most malignant bilious fevers, while the fevers in which Cinchona is administered are chiefly simple intermittents, for the most part unattended with danger. The natives use the bruised bark as a means of intoxicating fishes, which affords a very singular coincidence with what is mentioned by Dr. Saunders, by the same use being made of Cinchona Bark by the Peruvian Indians. Malambo Bark is supposed to be furnished by some plant allied to *Galipea*.

GA'LIUM (from γάλα, milk), a genus of Plants belonging to the natural order *Galiaceæ* or *Rubiaceæ*. The corolla is rotate, 4-parted; the fruit dry, not crowned with the calyx, and composed of two indehiscent 1-seeded mericarps. The species are branched herbs with variable inflorescence.

G. cruciatum, Crosswort, has elliptic oblong hairy leaves, four in a whorl; the flower-stalks lateral, corymbose, bracteated; terminal fertile flowers, mostly stamniferous; the fruit-stalks deflexed, and the fruit smooth. It is a native of Europe, and is commonly found in Great Britain.

G. mollugo, Great Hedge-Bedstraw, or Wild Madder, has about 8 leaves in a whorl, they are lanceolate-obovate or obovate-oblong; the margins rough with prickles pointing forwards; the branches of the panicle many-flowered, the lower ones spreading horizontally; the fruit glabrous. This species is a native almost throughout Europe and the Caucasus, and is found in Britain. The flowers are white, and sometimes yellowish. The roots are creeping, and yield a red dye like the true Madder, but of a brighter colour; they also have the property of colouring the bones of animals red that feed upon them. This plant has been extolled by M. Jourdan, the director of the hospital at Tain, in Dauphiny, as an effectual cure for epilepsy. It is however to be feared that the cases he details, which are certainly very marvellous, will not justify his reliance on this remedy.

G. tinctorium, the Dyer's Bedstraw, has smooth decumbent stems; linear-obtuse leaves, scabrous on the margin and keels; elongated axillary terminal and many-flowered peduncles. The corolla has 4 obtuse lobes, and the fruit is smooth and glabrous. This species is a native of North America, in low marshy places, especially in Canada and Newfoundland; it is also found in the Straits of De Fuca. It is very nearly allied to *G. trifidum*, but is distinguished by the stems being smooth and the flowers always 4-parted.

G. palustre, a native of Great Britain, nearly resembles *G. tinctorium* when the leaves are more numerous than usual. It is said that from the roots of this plant the Indians extract the red dye with which they colour their feathers and the ornaments of their dress.

G. septentrionale, the Northern Bedstraw, has erect tetragonal smooth stems; oblong lanceolate leaves, 4 in a whorl. The fruit is beset with hooked bristles; the flowers are numerous and of a milk-white colour. The Cree women use the root of this plant to dye red. It is a native of North America, about the lakes of Canada and the United States.

G. verum, Ladies' Bedstraw, or Cheese-Rennet, is distinguished by having its leaves about 8 in a whorl, linear-setaceous with revolute margins, channelled above, downy beneath. The flowers in numerous small dense panicles of a golden-yellow colour. On loose sandy soils the flowers are sometimes solitary and the stems much more branched, but agreeing in other respects with this species. It is a native of Europe and Siberia, in meadows, woods, and among bushes, and is found in Britain very commonly in dry soils. The stalks and flowers of this plant have been used in the cheese counties for the purpose of curdling milk, and also for colouring it. Mathiolus says it produces an agreeable flavour, and makes the cheese "eat sweeter." The French formerly used to prescribe the flowers in hysteria and epilepsy. The roots afford a rich red dye, superior in colour to madder. It was grown at one time as a substitute for the true Madder, *Rubia Tinctorum*, but the roots are too small to render its culture profitable. This plant seems to be the γάλιον of Dioscorides.

G. aparine, the common Goose-Grass, or Cleavers, has from 6 to 8 leaves in a whorl; they are linear-lanceolate, with marginal prickles pointing backwards; axillary 3-flowered peduncles; reflexed granulated fruit. It is a native throughout the whole of Europe, north of Asia, and North America, in hedges, fields, and most cultivated places; it is plentiful in Great Britain. This plant, according to Burnett, was fancifully called by the Greeks Philanthropos, as they attributed the readiness with which it cleaves to our habiliments to a love of the human species. A mechanical cause will however fully account for this tendency. It is thus it has acquired the names of Cleavers, Catch-Weed, &c., and from being a favourite food or medicine of geese that of Goose-Grass. Dioscorides relates that this plant was used by the shepherds of his time as a sieve to strain milk, and Linnæus tells us it is still made use of in Sweden for the same purpose. It is the ἀπαρίνη of Theophrastus. The expressed juice of this herb taken in doses of four ounces or a quarter of a pint night and morning, during several weeks, is said to be a very beneficial remedy in cutaneous disorders, and is believed by the country people to be a purifier of the blood and an antiscorbutic. The seeds have a corneous albumen, and when roasted have been used instead of coffee. We are not aware that they have been analysed, but it is not improbable that they contain a principle similar to caffein, and if this be the case they would form a valuable substitute for coffee. The roots of this species, like most of the genus, afford a rich red dye, and birds that feed on them have their bones tinged with the colour. The roots of *G. tuberosum* are farinaceous, and in China are cultivated as a dietetic vegetable. Loureiro says that when boiled they are both wholesome and nutritious. Don enumerates 164 species of *Galium*, which are distributed in every quarter of the world. The common name Bedstraw given to all the species is from the verb to 'strew,' anciently written 'straw.' Before the introduction of modern luxuries beds were made by strewing with various herbs, and doubtless this was one used for that purpose, and has thence acquired its common name. These plants are very easily cultivated and propagated; they will grow in any common soil, care being paid to the situations in which they are placed, which should as much resemble their natural positions as possible; those brought from marshes and bogs should have a moist soil, and the natives of warmer climates should be protected during the winter. None of them however are worth cultivation unless in botanical gardens.

(Fraas, *Synopsis Plant. Floræ Classicæ*; Don, *Dichlamydeous Plants*; Burnett, *Outlines of Botany*; Babington, *Manual of British Botany*.)

GALL. [BILE.]

GALL-BLADDER. [LIVER.]

GALLI'COLÆ, a family of Hymenopterous Insects of the section *Pupivora*. Distinguishing characters:—Posterior wings having but one nervure; anterior wings with two branchial cells, a radial cell of a triangular form; two or three cubital cells, of which the second (where there are three) is very small, and third large, and bounded by the apical margin of the wing; antennæ of equal thickness from the base to the apex (or with the latter portion slightly thickened), and consisting of from 13 to 15 joints. The males with one joint more to the antennæ than the females. Palpi long; the maxillary usually 4-jointed, and the labial 3-jointed. Ovipositor lodged in a groove on the under side of the body.

Latreille enumerates but three genera belonging to this family. Those which have the antennæ filiform, the abdomen much compressed, the radial cell of the wing long and narrow, the two brachials very distinct, and the first two cubitals small, constitute the genus *Ibalia*.

The species of the next genus (*Figites*) have the abdomen thickened and rounded above, the antennæ gradually thickened towards the apex, but one brachial cell, the radial very distant from the apex of the wing, and the second cubital wanting.

In the genus *Cynips* the abdomen is similar to the last, but the antennæ are filiform; there are three cubital cells to the wing, the first of which is large; the radial is elongated, and there is but one complete cell at the base of the wing. [GALLS.]

GALLI'NÆ, Gallinaceous Birds, the fifth order of the class *Aves*, according to Linnæus, who thus characterises it:—Bill (a reaping sickle, 'Harpa colligens') convex; the upper mandible arched over the lower; nostrils over-arched by a cartilaginous membrane. Feet formed for running; the toes rough below. Body sebaceous, muscular, delicate (purum). Food: grain collected on the earth and macerated in the crop (ingluvies). Nest artless and placed on the ground; eggs numerous; food pointed out to the young by their parent. Polygamous. Analogous to the order *Pecora* in the class *Mammalia*. [RASORES.]

GALLINSECTA. [COCCIDÆ.]

GALLINULA. [RALLIDÆ.]

GALLIONELLA, a genus of Plants belonging to the natural order *Diatomaceæ*, and to Kützing's family *Meloseireæ*. [MELOSEIREÆ.]

GALLS are the result of a morbid action excited in the leaf-buds of several species of the genus *Quercus*, or Oak.

The galls of commerce are chiefly those which occur on the *Quercus infectoria* (Ollivier). They vary in size from that of a pea to that of a nutmeg.

They originate in the puncture of an insect, *Cynips gallætinctoriæ*. The puncture is effected by the ovipositor of the insect, and an egg is at the same time deposited. An interruption in the ordinary functions of the tissues of the plant takes place at the spot where the egg is inserted; the consequence is an excrescence of vegetable matter, principally tannin, formed round the egg, and furnishes a nidus for the grub or larva when hatched. When this takes place the grub eats its way out through the side of the gall; after which the vitality of the excrescence either decreases or ceases altogether. The surface has irregular elevations or lines, with the interspaces generally smooth. The colour is white or yellow in one variety; green, gray, or black in another. The white variety, which is the largest, often has a hole in the substance of the shell by which the larva has escaped. This kind is the least powerful and least esteemed. The best Galls come from Aleppo and Smyrna, but are often mixed with those from Syria and Cyprus. In 100 parts of Aleppo Galls Sir H. Davy found gallic acid, 6·2; tannin, 26; gum and insoluble tannin, 2·4; lime and other salts, 2·4; woody fibre, 63. Braconnot also found ellagic acid. Galls are devoid of smell, but have a disagreeably bitter taste, with a powerfully astringent action. The whole of their soluble matter is yielded to forty times their weight of boiling water; ether dissolves about half their weight, alcohol considerably more.

They yield a fine black colour with any of the salts of iron, and are used in the preparation of writing ink. The quantity imported is annually about 700 tons. A kind of gall has lately been imported from China. Dr. Pereira describes it in the 'Pharmaceutical Journal' under the name of Woo-pei-tze; they are of very irregular shape, more bulky than the common galls, and hollow, the external shell being only about $\frac{1}{37}$ of an inch in thickness, very brittle, and of a brownish-yellow colour. Mr. Doubleday says that the producing insect in this case is one of the *Aphis* tribe. They are extremely astringent, but have not yet been used in dyeing.

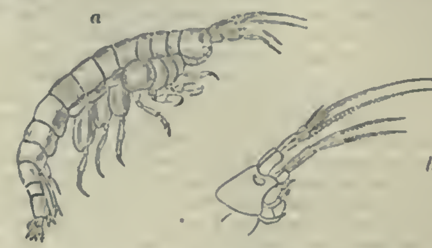
The infusion possesses all the valuable properties of the gall, as does an alcoholic tincture; but decoction is an objectionable preparation. For internal use the infusion is preferable to the powder, which, like all substances containing much woody fibre, irritates the stomach. Galls may be employed in powder to form an ointment, which with opium and camphor is of great service in painful hæmorrhoids. As a tonic in intermittent fever, and as an astringent in hæmorrhagic or other discharges, galls are occasionally employed. But the most extensive use is made of them in the arts, and as a chemical test.

GAMBOGE, GAMBOGIA. [GARCINIA; HEBRADENDRON.]

GA'MMARUS, a genus of Animals belonging to the Amphipodous Crustaceans, the Crevettes or Chevrettes of the French. It has the following characters:—Antennæ inserted in front of the head between the eyes, moderate, composed of three principal joints and a fourth which is setaceous, multiarticulate and terminal; the upper antennæ with a small, setaceous, multiarticulate appendage at the internal extremity of their third joint. The four anterior feet terminated by a large compressed hand provided with a strong hook or moveable finger, which applies itself upon the lower edge; the next four feet terminated by a single joint, or slightly curved nail; the last six longer, raised on the sides of the body, and with a delicate and straight terminal joint. There are long bifid very moveable filaments on each side under the tail, which is terminated by long, ciliated appendages, which are extended nearly in the direction of the body, and which constitute a sort of spring, by means of which the animal executes considerable leaps, or aids its swimming by a backward impulse on the water. Body oblong, very much compressed, arched, divided into thirteen segments (including the head); each segment furnished above with a crustaceous, delicate, semi-transparent, transverse lamina or blade, and the first seven also furnished with a lateral crustaceous piece which covers the base of the feet. (Desmarest.)

G. Pulex, Fabricius and Latreille (*Cancer Pulex*, Linnæus; *Squilla Pulex*, De Geer; *Squilla fluviatilis*, Merrett; *Gammarus aquaticus*, Leach; Crevette des Ruisseaux, Geoffroy), the Fresh-Water Shrimp. This crustacean, which abounds in springs and rivulets, always swims near the bottom on its side, and its progression is principally performed by the rapid jerks of the appendages of the tail. The animal is carnivorous and feeds principally on dead fishes, and often on the carcasses of its own species. The male may often be seen swimming coupled with the female, which is much smaller, and which he holds between his legs. She keeps her eggs till they are hatched, and the young for some time seek shelter under her abdomen and the lateral appendages of her body.

There are some marine species; and Desmaret observes that the genus bears the strongest analogies to those genera which have been separated from it, in his opinion on sufficiently slight grounds, under the names of *Leucothöe, Dexamine, Melita, Mæra, Pherusa, Amphithöe, Orchestia*, &c. The greater part of these, M. Desmaret states, have not been adopted by the more recent authors on the natural history of the Crustaceans; and the only ones which had been generally admitted when he wrote were *Talitrus* and *Corophium*. *Cerapus* of Say he considers to be founded on sufficient characters. M. Latreille however, in the fourth volume of Cuvier's 'Règne Animal' (ed. 1829), admits them all.



Fresh-Water Shrimp (*Gammarus Pulex*).
a, animal, magnified; *b*, the head and antennæ of the same, highly magnified.

Gammarus (*Amphipoda*) is noticed by Mr. Westwood as one of the types of each of the great groups of the typical Malacostracous *Crustacea*, which have been ascertained to undergo no change of form sufficiently marked to warrant the employment of the term metamorphosis. ('Phil. Trans.,' 1835.) [COROPHIUM.]

GAMPSONYX. [FALCONIDÆ.]

GANGA. [TETRAONIDÆ.]

GANNET. [PELECANIDÆ.]

GA'NODUS, a genus of Fossil Ganoid Fishes from the Oolite of Stonesfield; 7 species. (Egerton.) Referred to *Chimæra* by Agassiz.

GANOID, a grand division of Fossil Fishes in the classification of M. Agassiz. [FISH.]

GANYME'DA (Gray), a genus of Radiated Animals allied to the *Echinidæ* and the *Asteriadæ*, and which is thus characterised:—

Body hemispherical, depressed, thin, chalky, hollow. The back rounded, rather depressed, flattened behind, with a rather sunk quadrangular central space. The sides covered with sunken angular cavities, with a small round ring, having an oblong transverse subcentral hole in their base. Underside small, rather concave, with five slight sloping elevations from the angles of the mouth to the angles of the rather pentagonal margin. The edge simple. The mouth central. Vent none. Cavity simple. Parietes thin and minutely dotted; centre of the dorsal disc pellucid.

The genus, in Dr. Gray's opinion, is very nearly allied to Goldfuss's *Glenotremites paradoxus* ('Petrifact.' tab. 49, f. 9, and t. 51, f. 1), but Dr. Gray points out the differences, and is induced to consider these two genera as forming a family or order between the *Echinidæ* and *Asteriadæ*; allied to the latter in having only a single opening to the digestive canal, and agreeing with the former in shape and consistence, but differing from it in not being composed of many plates.

Dr. Gray only knew of two specimens of *Ganymeda*, which he believes were found on the coast of Kent, as he discovered them mixed with a quantity of *Discopora Patina*, which he collected several years ago from fuci and shells on that coast. Size of specimens one-eight of an inch in diameter. *Ganymeda pulchella* (Gray) is the name of the species. ('Zool. Proc.,' 1834.)

GAR-FISH, GAR-PIKE. [BELONE; ESOX.]

GARCI'NIA, a genus of Plants belonging to the natural order *Guttiferæ*, named in honour of Dr. Garcin, who travelled in the East Indies. It formerly consisted of few species, but no less than 21 are enumerated by Dr. Wallich, 10 of which he considers new. These are distributed over the islands of the Indian Archipelago, in the southern parts of China, in the Indian and Malayan peninsulas, in Asam and Silhet, with one species (G. Cowa) extending as far north as Monghir on the Ganges. They are all trees of considerable size, with opposite coriaceous shining oval leaves; numerous flowers, which are monœcious or diœcious; in the male, stamens numerous, inserted on a large fleshy 4-lobed receptacle, anthers bursting longitudinally; in the female, stamens numerous but imperfect, ovary 4-10-celled, ovules solitary. The fruit fleshy and juicy, crowned with the peltate stigma, is edible in many of the species.

G. Mangostana is the most remarkable species, being the far-famed Mangosteen (Mangees, Marsden) of the Malays, reckoned one of the most delicious of all fruits, and not alone of the countries where it is indigenous, but, as Marsden says, "is the pride of the Malay Islands, and perhaps the most delicate fruit in the world." It is a native of the Malayan Peninsula and of the islands to the eastward of the Bay of Bengal, forming trees of considerable size, with a straight trunk and numerous spreading opposite branches forming an elegant conical head. The tree is considered one of the most ornamental in Batavia for gardens, also as affording an agreeable shade. Bontius compares their appearance to that of citron-trees. It is in flower and fruit a great part of the year, according to Roxburgh, but Marsden says "the returns of its seasons are very irregular." So wedded is it to its indigenous soil and climate, that the innumerable attempts made to cultivate it elsewhere have uniformly failed. Dr. Roxburgh says, "For these 35 years past I have laboured in vain to make it grow and be fruitful on the continent of India. The plant has uniformly become sickly when removed to the north or west of the Bay of Bengal, and rarely rises beyond the height of two or three feet before it perishes." The male and female flowers are sometimes on the same, but usually on separate trees. The germ is superior, round, from 6- to 8-celled, with one ovule in each, attached to the middle of the axis. The ripe berry is spherical, of the size of a pretty large apple, having the surface even, and crowned with the permanent peltate 6- to 8-lobed stigma. The rind is thick, firm, though somewhat spongy, of a dull-crimson colour, sometimes compared to that of the pomegranate. Seeds as far as 8 in number inclosed in a very abundant soft fleshy envelope which is delicately white, forming the edible part of the fruit, described as delicious to the taste and as dissolving away in the mouth. It is also extremely innocent in its nature, as almost any quantity of it may be eaten without detriment, and persons sick of almost any disease are allowed to partake freely of it without inconvenience. The fruit before ripening is slightly acid. The rind is powerfully astringent, and its decoction is employed in dysentery and as a gargle in aphthæ of the mouth. The bark of the trunk and branches is also considered astringent, and said to be employed by the Chinese in dyeing.

G. cornea has oblong elliptic leaves, solitary and umbellate flowers, lateral, terminal, and drooping; the stigma entire; the berry the size of a plumb. It is a native of the East Indies in the high remote mountains of Amboyna. The trunk of this tree is very lofty, but not very thick, it is covered with a black bark. The branches extend wide, and divide into many short branches, which have a pair of leaves at each joint, these are large, from 11 to 15 inches long and 4 inches broad, but on old trees shorter, smooth, firm, and shining. The flower rises between the upper leaves, drooping, having the form of a small rose, of a yellow colour. The fruit is crowned by the entire stigma, which appears like a wart. It is of a dusky-brown or smoky colour on the outside, and within it has a mucous pulp, in which lie a few seeds in the shape of a half-moon. It has a resinous smell when fresh. The wood is heavy, and very hard like horn; it is used for the handles of tools, and the young ones in building, the old ones being too hard to work.

G. Cambogia has elliptic leaves tapering to both ends, terminal solitary flowers, yellowish corollas, an 8-lobed stigma, the berry 8-furrowed. It is a native of Malabar and other parts of the East Indies. It is a tall tree with a trunk as thick as two men can compass, with spreading opposite branches. The leaves are 5 inches long and half that in breadth. The fruit is about 2 inches in diameter, drooping on peduncles, 1 inch in length; the rind is thin, smooth, and yellowish, the pulp is yellow, succulent, sweet, and eatable. It is very common about Siam and Cambodia, where incisions are made in the bark, and a quantity of gum-resin, called Gamboge, flows out, and is exported to foreign countries.

It is called by the natives of Travancore Gharka Pulli, and is therefore inferred to be *Carca Pulli* of old writers. In Ceylon the fruit is called Goraka, and much used by the natives in their curries; when ripe it is said to form a fine fruit as large as the Mangosteen. Mrs. Colonel Walker, in her letters to Dr. Graham, describes the outer husk of the fruit as being prepared by the natives by taking out the pulp and seeds, bruising and then heaping it up until the whole is soft. It is then smoked and kept within the influence of smoke, being much used as a favourite ingredient in their curries and also for preserving, along with salt, a small kind of fish, which thus cured will keep for six or seven months.

The name *Cambogia* is derived from the province Camboja, or Cambodge, whence it comes.

G. Cambogia, *G. Cowa*, *G. lanceæfolia*, *G. Kydia*, *G. pedunculata*, and *G. paniculata*, all yield a kind of edible fruit, but of these the last is most like the Mangosteen. From incisions made in the branches a yellow juice exudes, and soon concretes, having a close resemblance to, and in fact forming an inferior kind of gamboge; whence it has been inferred that the commercial gamboge is yielded by tho species. Later investigations have proved the incorrectness of the opinion, and the true gamboge-tree of Ceylon has been determined to belong to a new genus named *Hebradendron*. [HEBRADENDRON.] *G. Zeylona*, *G. cornea*, and *G. pictoria* (the last also supposed to be a species of *Hebradendron*), all yield an inferior kind of gamboge.

GARDE'NIA (named after Dr. Alexander Garden of Charlestown, South Carolina, a correspondent of Linnæus), a genus of Plants belonging to the natural order *Cinchonaceæ*. It has the calyx usually ribbed, with a tubular truncate limb divided into several lobes or teeth; the corolla funnel-shaped, or approaching salver-shaped, with a tube much larger than the calyx, and a contorted spreading 5-9-parted limb; the anthers 5-9, linear, sessile in the throat; the stigma clavate, bifid, or 2-toothed, with thick erect lobes; the dissepiments of the ovary 2-5, incompletely dividing it into cells; the berry fleshy, crowned with the calyx, with a papery or bony lining, incompletely 2-5-celled; the seeds immersed in fleshy parietal placentæ. The species are armed or unarmed trees or shrubs, with axillary or terminal, usually solitary, white and fragrant flowers.

G. campanulata is a shrubby plant with short branches, spiny at the apex, the spines solitary; the leaves lanceolate, smooth, acuminated at both ends; the flowers on short pedicels in terminal and lateral fascicles; the limb of the calyx campanulate, with a short acutely 5-toothed border; the corolla sub-campanulate, 5-lobed; the berry, roundish, ovate. This plant is a shrub 5 to 10 feet in height, and is a native of the East Indies, in the forests of Chittagong. The berry, is about the size of a golden pippin apple, and is employed by the natives of India as a cathartic and anthelmintic.

G. arborea is an unarmed tree with ovate-oblong leaves, terminal, almost sessile flowers, usually arranged in threes; the corolla with a filiform tube and a 5-parted limb; the berry drupaceous, smooth, containing a 4-5-valved shell. It is a native of the East Indies. The fruit is eaten by the natives of India. It is one of the most beautiful species of the genus, and deserves a place in every collection.

There are about 50 species of *Gardenia*, which all bear elegant sweet-scented flowers. They thrive best in a mixture of loam, peat, and sand. Under the name of Cape Jasmines, double-flowered varieties of *G. florida* and *G. radicans* are extensively cultivated. Their flowers are very fragrant, and the best way of getting them to bloom freely is to set them in a close frame with a gentle bottom heat in the spring. In the winter they may be placed in the greenhouse. They may be increased by cuttings.

(Lindley, *Flora Medica;* Don, *Dichlamydeous Plants.*)

GARLIC. [ALLIUM.]

GARLIC-PEAR. [CRATÆVA.]

GARNET, a well-known precious stone, of which there are many varieties. Some of them are probably distinct species; but agreeing in form, and some other properties, they are classed together. This mineral occurs crystallised, massive, and granular. The primary form is a cube, but it occurs in the form of a rhombic dodecahedron. The colour is various, and accordingly, as will be seen below, it has received different names. It is transparent, translucent, rarely opaque. Lustre vitreous, resinous. Specific gravity, 3·6 to 4·2. Hardness, 6·5 to 7·5. Cleavage parallel to tho planes of the rhombic dodecahedron; fracture uneven.

This mineral occurs in the mountainous parts of most countries.

The massive varieties are amorphous, structure granular, compact. The crystalline varieties, according generally to their colour, have received various names. Precious Garnet, *Almandine;* black, *Melanite*, *Pyreneite;* greenish-yellow, *Grossularia;* yellow, crystallised, *Topazolite;* granular, *Succinite;* brownish-yellow, granular, *Colophonite;* greenish, compact, *Allochroite;* red, *Pyrope*, Carbuncle; reddish-brown, *Essonite*, Cinnamon-Stone, *Romanzovite;* magnesian, *Rothoffite.*

Tho following are the analyses of the *Almandine*, by the authors named, and from the places mentioned:—

	Bohemia.	New York.
Silica	33·75	42·51
Alumina	27·25	19·15
Oxide of Iron	36	33·57
Oxide of Manganese	0·25	5·49
Lime		1·07
	97·25 Klaproth	101·79 Wachtmeister.

It appears that the essential ingredients of the Garnet are silica, alumina, and oxide of iron; these are frequently partially replaced by oxide of manganese, lime, and magnesia.

Garnet occurs abundantly in mica-slate, hornblende slate, and gneiss, and less frequently in granite and granular limestone. It is found sometimes in serpentine and lava.

The best precious Garnets are from Ceylon and Greenland. *Grossularite* occurs in the Wilin River, Siberia, and at Tellemarken in Norway; green Garnets are found at Swartzenburg, Saxony; *Melanite* in the Vesuvian Lavas; *Ouvarovite* at Bissersk in Russia; *Topazolite* at Mussa, Piedmont; *Aplome* in Siberia on the Lena, and at Swartzenburg. Garnets also occur in several parts of the United States.

The Garnet is the Carbunculus of the Romans. The Alabandic Carbuncles of Pliny were so-called because they were cut and polished at Alabanda. Hence the name *Almandine.*

The clear deep red Garnets make a rich gem, and are much used for ornament. Those obtained from Pegu are most valued. They are cut quite thin on account of their deep colour. Cinnamon-Stone is also used for the same purposes. Garnet when powdered is used for the same purposes as emery.

(Dana, *Mineralogy.*)

GARROT. [DUCKS.]

GARRULUS. [CORVIDÆ.]

GARRYA, the only genus and type of the natural order of Incomplete Plants, *Garryaceæ*. It was named by Mr. Douglas in compliment to Nicholas Garry, Esq., secretary to the Hudson's Bay Company. Tho flowers of this genus are unisexual, the staminiferous and pistiliferous flowers being upon distinct plants. The staminiferous flowers are in pendulous catkin-like racemes, within connate bracteæ. They have a 4-leaved calyx and 4 stamens. The pistiliferous flowers are in pendulous racemes like the others, but with a 2-toothed calyx, connate with the ovary, which is 1-celled. They have two setaceous styles, two pendulous ovules, with funiculi as long as themselves. The fruit is a berried pericarp, not opening, and containing two seeds. The embryo is very minute in the base of a great mass of fleshy pulp. The leaves are simple, opposite, exstipulate, evergreen, serrated or entire. The species are shrubs, natives of California and Mexico. Only two species of this genus have been introduced into Great Britain; they are very ornamental and grow best in a loamy soil, and may be propagated by layers.

G. elliptica, the Elliptic-Leaved Garrya, has, when young, soft pubescent purplish branches; when older, they become smooth and grayish. The leaves are dark-green, shining above, hoary beneath, with simple twisted, interwoven hairs. The flowers are of a greenish or yellowish-white, and are in bloom from November to February. Only the stamen-bearing plant is in this country. During the season of blossoming this shrub presents a striking and beautiful appearance, with its delicate pendulous catkins, which are from eight inches to a foot in length. It is easily cultivated in our gardens, and is as hardy as the common laurustinus.

G. laurifolia has elliptic oblong leaves either entire or very minutely dentate. Both the staminiferous and pistiliferous flowers are solitary, sessile, and opposite, having one in every bract. This species, like the former, is an evergreen shrub or low tree, and grows on the mountains of Mexico. According to Loudon there is but one specimen of this very beautiful and desirable shrub preserved in the garden of the Horticultural Society. It was brought over in the year 1839. There are some other species of *Garrya* recognised by various botanists: *G. Lindleyi*, considered by Mr. Bentham as a variety of *G. laurifolia; G. macrophylla, G. oblonga*, and *G. ovata* are described in Bentham's 'Plantæ Hartwegianæ' from specimens collected by Mr. Hartweg in different parts of Mexico.

(Loudon, *Encyclopædia of Trees and Shrubs.*)

GARRYACEÆ, *Garryads*, a small natural order of Plants related to *Juglandaceæ, Caprifoliaceæ*, and *Helwingiaceæ*. The species are shrubs with opposite leaves without stipules. The flowers are arranged in pendulous amentaceous racemes within connate bracts. The wood is without distinct concentric zones or dotted ducts. The flowers are unisexual and amentaceous. There are four stamens alternate with the four sepals, not elastic. The pericarp is berried, indehiscent, 2-seeded; the embryo very minute, in the base of a fleshy albumen. The two genera of this family are *Garrya* and *Fadgenia*. They are found in North America in temperate latitudes, or in the West Indies. They have the appearance and habit of viburnums or dogwoods.

GARVIE, a local name for the Sprat. [CLUPEIDÆ.]

GASTEROMYCE'TES, a sub-order or cohort of Plants belonging to the natural order *Fungi*. [FUNGI.] It is distinguished from the higher forms of *Fungi* [HYMENOMYCETES] by the reproductive organs being included in a case of some kind or another.

The first tribe of the *Gasteromycetes* is *Angiogastres*. Of this tribe there are four sub-tribes or sections. The first, *Phalloidei*, has a distinct receptacle at length bursting through the excipulum. Of this section the genus *Phallus* is the type. [PHALLUS.]

The second section is *Tuberaceæ*. [TUBERACEÆ.]

The third section, *Nidulariaceæ*, has a receptacle filled with free or elastically pedicellate sporangia. The type of this section is *Nidularia*, or Bird's-Nest Peziza. There are three species of this genus found in Great Britain. [NIDULARIACEÆ.]

The fourth section, *Carpoboli*, have a solitary sporangium protruding from the receptacle. The genera belonging to it are *Carpobolus, Sphærobolus, Thelebolus, Pilobolus, Atractobolus.*

A species of the last named, *A. ubiquitarius*, is found on wood, stones, and other things, after rain, appearing like scattered meal. The Rev. M. J. Berkeley says however that he is convinced that it is of insect origin. *Sphærobolus stellatus* is found on rotten wood and sticks, in the autumn. In its early state it is covered by a fine woolly or cottony web, which is very fugacious. When the young plants have pushed through this web, they have the appearance of mustard-seeds. Each plant consists of an outer and an inner membrane. At the time of the opening of the outer membrane, the inner one, which is then concave, and with its mouth uppermost, projects the ball of sporules which it contains, like a bomb from a mortar, to a distance of several inches. The cracking noise occasioned by this phenomenon is so great as to be distinctly audible at some distance. "This is unquestionably," says Dr. Greville, "the most wonderfully constructed plant which it has fallen to my lot to describe. That so great a degree of force should exist in a body not larger than a pin's head, and that force exerted in defiance of considerable resistance, seems to surpass the power of anything to account for it satisfactorily."

The tribe *Pyrenomycetes* is frequently regarded as a sub-order or cohort. [FUNGI.] It consists of genera having more or less the characters of *Sphæria*. [SPHÆRIA.] Most of the species are found on the decaying leaves of other plants, and vary with the species of the plant on which they grow. The genera in which the greatest number of species have been described by British botanists are *Cytispora, Phoma, Dothidea, Asteroma, Rhytisma, Phacidium, Hysterium*, and *Leptostroma*. [PYRENOMYCETES.]

The third tribe is *Trichospermi* [TRICHOSPERMI]; the fourth, *Trichodermacei*. [TRICHODERMACEÆ.]

The fifth tribe, *Perisporiacei*, has a peridium scarcely distinct from the nucleus, and the sporidia immersed in pulp, free or included in peridiola. The genera in this tribe are not numerous. *Racodium*, the Mouse-Skin Byssus, is placed here by some authors; by Fries in *Byssaceæ*. [BYSSACEÆ.]

The most extensive genus is *Erysiphe*, the species of which produce various forms of mildew. It has a fleshy peridium opening at the collapsing apex, sub-gelatinous within; the sporidia included in one or more peridiola, often including sporidiola; the thallus floccose, effused, free.

E. pannosa, the Rose-Mildew, is found on the leaves of the various species of rose. It is easily known by its shining clothy aspect, which is very different from the rest of the genus. On this account it is referred by Fries to *Eurotium*.

E. communis is an extremely common fungus, and is found on various kinds of herbaceous plants. It is not improbable that the various forms of *Erysiphe*, which have been described according to the species of plant on which they grow, have a common origin. The same may be said of the forms of *Uredo, Æcidium*, and *Puccinia*. [MILDEW; UREDO.]

The sub-order *Hyphomycetes* of Berkeley and others includes many of the genera that are referred by Fries to the fourth order, *Coniomycetes*. The first tribe, *Cephalotrichei*, includes the genera *Isaria, Anthina*, and *Ceratium*. The species of the first two are not numerous or common. *Ceratium hydnoides* is not uncommon on rotten wood.

The tribes *Mucori, Dematiei*, and *Mucedines* consist of various genera of plants forming moulds, mildews, blights, brands, &c. [MILDEW; MOULDINESS; SPORENDONEMA.] Some of the species placed in these tribes by Berkeley are described under BYSSACEÆ.

The tribe *Sepidoniei* includes the genera *Sepidonium, Epochnum, Psilonia*, and *Fusisporium*. They have all a floccose mycelium, without any distinct sporidiferous filaments; and the sporidia, heaped together, lying upon and in general springing from the matrix. The species of *Fusisporium* are found in decaying fruits and vegetables. [FUNGI; ENTOPHYTA.]

The last sub-order, *Coniomycetes*, embraces those *Fungi* whose sporidia are produced beneath the epidermis of plants, and which in many instances appear to be rather diseases of the tissue than independent existences. The first sub-section or tribe is *Tubercularini*. [TUBERCULARINI.] The second tribe, *Stilbosporei*, consists of sporidia glued together into a nucleus, without any covering, under the cuticle of plants, at length bursting forth together with the gelatine or free. The genera of this tribe are *Nemaspora, Septoria, Stilbospora, Didymasporium*, and *Melancorium*.

The third tribe, *Sporidesmiei*, have their sporidia chained together into flocci. The genera are *Aregma, Torula*, and *Spilocæa*.

The fourth tribe, *Hypodermii*, includes those species of *Fungi* which are found underneath the cuticle of living plants. They are said by Fries to have "no proper vegetation, their sporidia arising from an anamorphosis of the cells of living vegetables." To this definition Berkeley objects, and regards the species as distinct plants. The principal genera are *Puccinia, Æcidium*, and *Uredo*. [ÆCIDIUM; UREDO.]

GASTERO'PODA, the third class of Mollusks, according to the system of Cuvier, who remarks that it is very numerous, and that an idea may be formed of it from the Slugs and Shell-Snails. Before we proceed to the sections, or rather orders, into which Cuvier has subdivided this extensive congregation, it will be necessary to put the reader in possession of his views of the conformation necessary to bring a molluscous animal within the class of Gasteropods.

These mollusks generally creep upon a fleshy disc placed under the belly; but which sometimes takes the form of a furrow or that of a vertical plate. The back is furnished with a mantle, which is more or less extensive, presents diversities of form, and, in the greatest number of genera, produces a shell. The head, placed in front, shows itself more or less, according to its greater or less retirement under the mantle, and is furnished with small tentacles, which are above the mouth, and never surround it. Their number ranges from two to six, and they are sometimes altogether wanting. Their proper use is only for touching, and, at the most, for smelling. The eyes are very small, sometimes adhering to the head; sometimes at the base, or at the side, or at the point of the tentacle; and sometimes these organs are altogether wanting. The position, the structure, and the nature of the respiratory organs vary, and afford grounds for dividing the animals into many families; but they never have any other than a single aortic heart, that is to say, placed between the pulmonary vein and the aorta. The site of the apertures by which the organs of generation come out and that of the vent vary; but they are nearly always on the right side of the body.

Many of the Gasteropods are absolutely naked; others have only a concealed shell; but the greater number carry a shell, which is capable of receiving and sheltering them.

These shells are produced in the thickness of the mantle; some of them are symmetrical, consisting of more pieces than one; others are symmetrical, but formed of a single piece; and there are also some non-symmetrical, which in species where they are very concave, and where they grow a long time, necessarily produce an oblique spire. If the reader will imagine an oblique cone in which other cones are successively placed, always larger in a certain direction than in the others, it will follow that the whole rolls itself upon the side which is least. The part on which the cone is rolled is called the Columella, or Pillar: this is sometimes solid, and sometimes hollow. When it is hollow, the open end of it is named the Umbilicus. The whorls of the shell may remain nearly on the same plane, or may extend towards the base of the columella. In the last case, the preceding whorls are raised one above the other, and form what is called the Spire, which is pointed in proportion to the more rapid descent and small enlargement of the whorls. Those shells with an elongated or projecting spire are termed Turbinated Shells. When, on the contrary, the whorls remain nearly on the same plane, and are not enveloped one within another, the spire is flat or even concave. These are called Discoid Shells. When the upper part of each whorl envelops the preceding ones, the spire is said to be concealed. That part of the shell from which the animal comes forth is termed the Aperture. When the whorls remain nearly on the same plane, the animal, when it creeps, carries its shell disposed vertically, the columella lying across the posterior part of the back; and its head passes under the border of the aperture opposed to the columella. When the spire is elongated it is directed obliquely to the right in almost all the species: a small number only have it directed to the left when they creep; these shells are called Reversed or Left-Handed Shells. The heart is always on the side opposite to that where the spire is directed. It is therefore ordinarily on the left side; in the reversed or left-handed shells it is on the right. The contrary of this disposition holds good with regard to the organs of generation.

The organs of respiration, which are always situated in the last whorl of the shell, receive the ambient element under its edge, sometimes by means of the mantle being entirely detached from the body along the whole length of this edge, sometimes in consequence of its being merely pierced by a hole. The border of the mantle is sometimes prolonged into a canal, so that the animal can advance to seek the surrounding fluid without exposing either its head or foot beyond the shell. For this purpose the shell, in such cases, has also on its edge, near to that end of the columella (the base) which is opposed to that whereto the spire tends (the apex), a notch or a canal for the lodgment of that of the mantle. The canal is consequently on the left in the ordinary species, and on the right in the reversed shells. The animal being very flexible is able to vary the direction of its shell, and most frequently when there is a notch or a canal it is directed forwards; the spire is thus behind, the columella on the left, and the opposite border, or external lip, as it is termed by some conchologists, on the right. A directly contrary disposition is manifested in the Reversed Shells, and these, in consequence of this contrary disposition, turn towards the left instead of turning towards the right, as in the normal structure. It follows as a consequence that the aperture of the shell, which is formed principally by the last whorl, is more or less large in proportion to the other whorls, accordingly as the head or foot of the animal, which is to be constantly protruded therefrom and retracted thereunto, is more or less voluminous compared with the mass of the viscera which remain fixed within the shell. The aperture is moreover wider or narrower in proportion as the same parts are more or less thick. There are shells whose aperture is narrow and long; the foot, in such cases, is delicate, and doubles together for the purpose of re-admission. The greater number of aquatic Gasteropods with a spiral shell have an Operculum, or separate piece, which is sometimes horny, sometimes calcareous, attached on the posterior part of the foot, and which shuts the shell when the animal has re-entered it and is entirely retracted within.

Cuvier, in continuation, remarks that there are Gasteropods with the sexes separate, and others which are hermaphrodites: of these last some have the power of reproduction without the aid of a second individual, while the others require a reciprocal copulation for the continuation of the species. He adds that the organs of digestion present as many differences as those of respiration, and he divides the class into the following orders:—

1. Les Pulmonés, *Pulmonifera* (*Pulmobranchiata* of De Blainville).

This order is distinguished from the Mollusks inasmuch as they respire the elastic atmospheric air by means of a hole opened under the border of their mantle, and which they dilate or contract at their pleasure. They have consequently no branchiæ, or gills, but only a net-work of pulmonary vessels, which creep around the walls and principally upon the plafond of their respiratory cavity. Some are terrestrial, others aquatic; but these last are obliged to come to the surface of the water from time to time, in order to open the orifice of their pectoral cavity for the purpose of respiration.

The Terrestrial Pulmoniferous Mollusks have all four tentacles; two or three only, of very small dimensions, have not permitted the observer to see the lower pair. They are divided into those which are naked, and those which are protected by a shell. They are all hermaphrodites.

Those which have no apparent shell formed the great genus *Limax* of Linnæus; and of these every one may find examples in the common slugs. [LIMAX.]

Parmacella and *Testacella* lead the way to those which have a complete and apparent shell, the borders of whose aperture, in the majority of instances, are reflected into a little roll (bourrelet) when the animal is adult. These were placed by Linnæus under his great genus *Helix*. The shell varies much in form; being for instance subglobular or subdiscoid, as in many of the shell-snails; or elongated and pyramidal, as in *Bulinus*, &c. [HELICIDÆ.]

The Aquatic Pulmoniferous Mollusks have only two tentacula, and always come to the surface to breathe; they do not therefore inhabit deep waters, but live for the most part in the fresh waters or salt lakes, or at least near the sides and mouths of rivers.

Cuvier goes on to give *Onchidium*, Buchanan (*Peronia* of De Blainville) [NUDIBRANCHIATA], as an example of the Aquatic Pulmoniferous Mollusks without shells.

Those with shells, which are sometimes discoid, as in *Planorbis*, or elongated and pyramidal, as in *Limnæa*, &c., he illustrates by the genera *Physa*, *Scarabæus*, *Auricula*, and *Conovulus*.

2. *Nudibranchiata* (*Polybranchiata—Tritonia*, &c., of De Blainville).

The Mollusks composing this order have no shell nor any pulmonary cavity; but their branchiæ are naked, and placed upon some part of the back. They are all hermaphrodites and marine. They often swim reversed, with the foot concave like a boat, at the surface, aiding their progression with their mantle and tentacles as with oars.

3. *Inferobranchiata*.

This order presents nearly the same form and organisation as the *Dorides* and *Tritoniæ*: but their branchiæ, instead of being placed upon their backs, are arranged in two long rows of leaflet-like appendages on each side of the body under the projecting border of the mantle. *Phyllidia* and *Diphyllidia*, Cuvier, belong to the *Inferobranchiata*.

4. *Tectibranchiata* (*Monopleurobranchiata* of De Blainville).

This order has the branchiæ attached either along the right side or upon the back, in the form of leaflets, which are more or less divided, but not symmetrical. The mantle covers the branchiæ more or less, and almost always contains in its thickness a small shell. The *Tectibranchiata* approach the *Pectinibranchiata* in the form of the organs of respiration, and live like them in the sea; but the *Tectibranchiata* are all hermaphrodites, like the *Nudibranchiata* and *Pulmonifera*. The genera *Pleurobranchus*, Cuv., *Pleurobranchæa*, Meckel, *Pleurobranchidium*, De Blainville; *Aplysia*, Linn.; *Dolabella*, Lam.; *Notarchus*, Cuv.; *Bursatella*, Blainv.; *Akera*, Müll.; *Bullæa*, Lam.; part of *Bulla*, Linn.; *Gasteroptera*, Meck.; *Umbrella*, Lam.; *Gastroplex*, Blainv.;—belong to this order. [BURSATELLA; BULLIDÆ; TECTIBRANCHIATA; PATELLIDÆ.]

5. *Heteropoda*, Lam. (*Nectopoda*, Blainv.).

Distinguished from all the others, inasmuch as their foot, instead of forming a horizontal disc, is compressed into a muscular vertical plate, which serves them as a fin, and at the edge of which, in many species, a dilatation, in form of a hollow cone, represents the disc of the other orders. Their branchiæ, formed of feathery lobes, are situated on the posterior part and left side of the back, directed forwards; and immediately behind them are the heart and a liver of no great size, with a part of the viscera and the internal organs of generation. Their body, lined with a muscular coat, is elongated, terminating most frequently by a compressed tail. Their mouth is formed by a muscular mass, and is furnished with a tongue beset with small hooks. The œsophagus is very long, the stomach delicate in texture, and two tubes at the right side of the packet of viscera give exit to the excrements and to the ova or to the prolific fluid. They generally swim with the back downwards and the foot above, and they can swell out their bodies by filling them with water by means which are not as yet well understood.

To this description Cuvier adds, that the method of swimming above described having induced Péron to believe that the natatory plate was on the back, and the heart and branchiæ under the belly, has given rise to many errors as to the proper place of these animals. Cuvier adds, that the examination of their nervous system led him to the opinion expressed in his memoir on the *Mollusca*, that they were analogous to the Gasteropods. A more complete dissection, he observes, made since, and that given by Poli, in his third volume, have completely confirmed this conjecture, and he states that the fact is that the *Heteropoda* differ but little from the *Tectibranchiata*. M. Laurillard believes that the sexes are always separate. Cuvier also remarks, that M. De Blainville makes of his (Cuvier's) *Heteropoda* a family which he names *Nectopoda*, and unites them with another family which he names *Pteropoda*, and which comprehends none of Cuvier's *Pteropoda*, except *Limacina*. To this, Cuvier observes, M. de Blainville refers *Argonauta*, upon what conjecture Cuvier knows not.

Forskal places all the *Heteropoda* of Cuvier under his genus *Pterotrachea*. [CARINARIA; ATLANTIA; HETEROPODA.]

6. *Pectinibranchiata* (*Paracephalophora Dioica*, Blainv.).

This order is by far the most numerous division of the Gasteropods, for it embaces nearly all those which have spiral univalve shells, and many of those whose shells are simply conical. Their branchiæ, composed of numerous leaflets or fringes (lanières) ranged in parallel order like the teeth of a comb (whence their name), are attached upon one, two, or three lines, according to the genus, to the plafond of the pulmonary cavity, which occupies the last whorl of the shell, and which forms a large opening between the border of the mantle and the body. Two genera only (*Cyclostoma* and *Helicina*) have, in the place of branchiæ, a vascular net covering the plafond of a cavity similar in other respects: these are the only genera which breathe air; all the others respire water.

All the *Pectinibranchiata* have two tentacula, and two eyes sometimes carried on their proper peduncles, a mouth in form of a proboscis, which is more or less elongated, and the sexes separate. The intromissive organ of the male, which is attached to the side of the neck, cannot ordinarily be retracted into the body, but is reflected in the branchial cavity, and is sometimes very large, as may be seen in the figure of *Buccinum undatum* [ENTOMOSTOMATA; BUCCINUM], which will give a general idea of the form of a marine Pectinibranchiate Testaceous Mollusk with a turbinated shell. *Paludina*, indeed, can cause this organ to re-enter the body by an orifice pierced at its right tentacle. The rectum and oviduct of the female creep also along the right side of the branchial cavity, and between them and the branchiæ is a particular organ composed of cellules containing a very viscous liquor, serving to form a common envelopment or case, which includes the eggs, and which the animal deposits with them. Several of these deposited ovaries present very complicated and singular forms, and may be often found on the sea-beach.

The tongue of the *Pectinibranchiata* is armed with small hooks, and files down the hardest bodies by slow and repeated friction.

The greatest difference among these animals consists in the presence or absence of the canal formed by a prolongation of the border of the pulmonary cavity of the left side, and which passes by means of a similar canal, or by a notch in the shell, so as to enable the animal to respire without leaving the shelter of its shell. Some of the genera again are without an operculum; and the species also exhibit differences in the filaments, fringes, and other ornaments exhibited on their head, their foot, or their mantle. These mollusks are arranged under many families, according to the form of their shells, which, generally speaking, present a sufficiently constant relation to the form of the animal. But the student should remember that this is not a rule without exception, as Dr. Gray has pointed out in his interesting paper in the 'Philosophical Transactions.'

In this work the reader will find the numerous genera—the leading ones at least—of this most extensive order, principally under the titles of the different families into which they have been separated by zoologists, and sometimes under their generic appellations.

7. *Tubulibranchiata.*

Cuvier considers that this order should be detached from the *Pectinibranchiata*, to which they nevertheless bear great resemblance, because their shell (which is in the form of a tube more or less irregular, the commencement of which only is turbinated or spiral) is fixed to different foreign bodies; they have in consequence no true copulative organs, and fecundate themselves. *Vermetus*, *Magilus*, and *Siliquaria* (all marine) belong to this order.

8. *Scutibranchiata* (*Paracephalophora Hermaphroditica*, with exception of the Chitons, De Blainv.).

This order consists of the Gasteropods which bear a near relationship to the *Pectinibranchiata* in the shape and position of the branchiæ, as well as in the general form of the body, but which have the sexes united in the same individual. The shells of this order are always without an operculum, very wide in the opening (some of them may be said to be almost all aperture), and many of them have shells without any turbination, so that they cover the animal, and especially its branchiæ, like a shield. The heart is traversed by the rectum, and receives the blood by two auricles, as in the generality of Bivalves. Under this order Cuvier, in his last edition of the 'Règne Animal,' places the *Haliotidæ* (Ear-Shells), *Stomatia*, *Fissurella*, *Emarginula*, and *Parmophorus*. [FISSURELLIDÆ; PATELLIDÆ.]

9. *Cyclobranchiata* (*Cervicobranchiata*, Blainv.).

Branchiæ in form of small leaflets or little pyramids, attached in a cordon more or less complete under the borders of the mantle, nearly as in the *Inferobranchiata*, from which the *Cyclobranchiata* are distinguished by their hermaphroditism; for they have no organs of copulation, and can reproduce the species without having recourse to a second individual. The heart does not embrace the rectum, but it varies in situation. [CHITONIDÆ; PATELLIDÆ.]

A general view of the structure and relations of the Shell-Fish is given under MOLLUSCA.

The following is a synopsis of the families and genera of *Gasteropoda* as given in Mr. Woodward's 'Manual of the Mollusca':—

Order PROSOBRANCHIATA.

Section A. *Siphonostomata.*
Family 1. *Strombidæ.*
Genera, *Strombus, Pterocerus, Rostellaria, Seraphys.*
Family 2. *Muricidæ.*
Genera, *Murex, Pisania, Ranella, Triton, Fasciolaria, Turbinella, Canedlaria, Trichotropis, Pyrula, Fusus.*
Family 3. *Buccinidæ.*
Genera, *Buccinum, Pseudoliva, Anolax, Halia, Terebra, Eburna, Nassa, Phos, Ringicula* (?), *Purpura, Purpurina, Monoceros, Pedicularia, Ricinula, Planaxis, Magilus, Cassis, Oniscia, Cithara, Cassidaria, Dolium, Harpa, Columbella, Oliva, Ancillaria.*
Family 4. *Conidæ.*
Genera, *Conus, Pleurotoma.*
Family 5. *Volutidæ.*
Genera, *Voluta, Cymba, Mitra, Volvaria, Marginella.*
Family 6. *Cypræidæ.*
Genera, *Cypræa, Erato, Ovulum.*
Section B. *Holostomata.*
Family 1. *Naticidæ.*
Genera, *Natica, Sigaretus, Lamellaria, Narica, Velutina.*
Family 2. *Pyramidellidæ.*
Genera, *Pyramidella, Odostomia, Chemnitzia, Stylina, Loxonema, Machrocheilus.*
Family 3. *Cerithiadæ.*
Genera, *Cerithium, Potamides, Nerinæa, Fastigiella, Aporrhais, Struthiolaria.*
Family 4. *Melaniadæ.*
Genera, *Melania, Paludomus, Melanopsis.*
Family 5. *Turritellidæ.*
Genera, *Turritella, Aclis, Cæcum, Vermetus, Siliquaria, Scalaria.*
Family 6. *Litorinidæ.*
Genera, *Litorina, Solarium, Phorus, Lacuna, Litiopa, Rissoa, Skenea, Truncatella, Lithoglyphus.*
Family 7. *Paludinidæ.*
Genera, *Paludina, Ampullaria, Amphibola, Valvata.*
Family 8. *Neritidæ.*
Genera, *Nerita, Pileolus, Neritina, Navicella.*
Family 9. *Turbinidæ.*
Genera, *Turbo, Phasianella, Imperator, Trochus, Rotella, Monodonta, Delphinula, Adeorbis, Enomphalus, Stomatella, Broderipia.*
Family 10. *Haliotidæ.*
Genera, *Haliotis, Stomatia, Scissurella, Pleurotomaria, Murchisonia, Trochotoma, Cirrus, Ianthina.*
Family 11. *Fissurellidæ.*
Genera, *Fissurella, Puncturella, Rimula, Emarginula, Parmophorus.*
Family 12. *Calyptræidæ.*
Genera, *Calyptræa, Crepidula, Pileopsis, Hipponyx.*
Family 13. *Patellidæ.*
Genera, *Patella, Aemæa, Gadinia, Siphonaria.*
Family 14. *Dentaliadæ.*
Genus, *Dentalium.*
Family 15. *Chitonidæ.*
Genus, *Chiton.*

Most of the families and more important genera are given under their proper names in this work.

GASTEROSTEUS, a genus of Fishes, with hard cheeks, belonging to the division *Acanthopterygii*. The common name of the species in this country is Stickleback. This genus is distinguished by the following characters:—Anterior dorsal represented only by free spines; body generally scaleless, but protected more or less at the sides by shield-like plates; ventrals reduced to a single spine; head without spines or tubercles; branchiostegous membrane with three rays.

Several species of Stickleback are found in the ponds and streams of this country, and one species is found in the salt-water; they are very active and voracious, and live upon aquatic insects and worms.

The most common species is the Three-Spined Stickleback (*Gasterosteus aculeatus*, Linn.), which is distinguished by the body being protected at the sides with shield-like plates, and the possession of three spines on the back. It is of an olive-colour above and silvery-white beneath, and varies from 2 to 3 inches in length. In the breeding season the males assume a pink hue on the under parts of the body, and the general colouring of the upper parts is brighter, and often green. According to Bloch this species spawns in April and June; and according to Cuvier in July and August.

The number of scaly plates varies in the sides of the body, and is supposed by some authors of high authority to afford specific characters. The following are the principal varieties or species established by Cuvier and Yarrell chiefly upon this character.

G. trachurus, Rough-Tailed Stickleback. (Yarrell, 'Brit. Fishes,' vol. i. p. 76.) The scaly plates extending the whole length of the sides; in number about 30.

G. semiarmatus, Half-Armed Stickleback (Yarrell). Lateral plates extending to a vertical line joining the vent and commencement of the soft dorsal; in number from 12 to 15.

G. leiurus, Smooth-Tailed Stickleback (Yarrell). Lateral plates extending only as far as the ends of the rays of the pectoral fins, where these last are laid back.

G. brachycentrus, Short-Spined Stickleback (Yarrell). Lateral plates not extending beyond the pectorals; dorsal and ventral spines very short.

The above are regarded as varieties of the *Gasterosteus aculeatus*, Linn., by Mr. Jenyns, who observes that that species "is subject to great variation, not only in the number of lateral plates, but in several other less obvious respects. The former may occasionally be found of every intermediate number between that which characterises the *G. leiurus*, Cuv., and that which appears in the *G. trachurus* of the same author. This number moreover is sometimes found constant in specimens which differ remarkably in other respects; at other times varying, when all other characters remain the same. From these circumstances combined, I feel satisfied that the above are mere varieties, notwithstanding the high authorities on which they stand recorded as distinct species." ('Manual of British Vertebrate Animals,' p. 349.)

A writer in the 'Magazine of Natural History,' vol. iii. p. 329, relates some interesting observations illustrative of the habits of these little fishes whilst in confinement in a tub. "When a few are first turned in, they swim about in a shoal, apparently exploring their new habitation. Suddenly one will take possession of a particular corner of the tub, or, as it will sometimes happen, of the bottom, and will instantly commence an attack upon his companions; and if any one of them ventures to oppose his sway, a regular and most furious battle ensues; the two combatants swim round and round each other with the greatest rapidity, biting and endeavouring to pierce each other with their spines, which on these occasions are projected. I have witnessed a battle of this sort which lasted several minutes before either would give way; and when one does submit, imagination can hardly conceive the vindictive fury of the conqueror, who, in the most persevering and unrelenting way, chases his rival from one part of the tub to another, until fairly exhausted with fatigue. They also use their spines with such fatal effect, that, incredible as it may appear, I have seen one during a battle absolutely rip his opponent quite open, so that he sank to the bottom and died. I have occasionally known three or four parts of the tub taken possession of by as many other little tyrants, who guard their territories with the strictest vigilance; and the slightest invasion invariably brings on a battle. These are the habits of the male fish alone; the females are quite pacific; appear fat, as if full of roe; never assume the brilliant colours of the male, by whom, as far as I have observed, they are unmolested."

Dr. James Stark discovered near Edinburgh a new species of the present genus, which greatly resembles the common species, but is rather smaller, and has four spines on the back. It is the *G. spinulosus* (Four-Spined Stickleback) of Yarrell and Jenyns.

A still smaller species—the Ten-Spined Stickleback (*G. pungitius*, Linn.)—is distinguished, as its English name implies, by the possession of ten spines on the back, and these are short and of equal length.

This, as well as the other species of the genus, is occasionally found in the salt-water. It appears to be pretty generally distributed throughout England.

Lastly may be noticed the Fifteen-Spined Stickleback (*G. spinachia*, Linn.), which is also found in England, a comparatively large species, being 5 or 6 inches in length, of an elongated and slender form, and having the snout much produced. The fifteen spines on the back are small and short; the fins are proportionally large.

This species appears to be confined to the salt-water, and feeds upon small *Crustacea*, as well as the eggs and fry of other fishes. It constitutes the sub-genus *Spinachia*, and is the *Spinachia vulgaris* of Fleming.

GASTRIC JUICE or ACID. [DIGESTION.]

GASTROBRANCHUS. [PETROMYZIDÆ.]

GASTROCHÆ'NA, a genus of Acephalous *Mollusca* belonging to the order *Lamellibranchiata*. It was established by Spengler. Lamarck places it between *Pholas* and *Solen*, and Cuvier between *Fistulana* and *Teredina*. M. Deshayes, in his edition of the 'Animaux sans Vertèbres,' says that it is evident that Lamarck came to very erroneous conclusions as to this genus. The animal, observes M. Deshayes, has two posterior very short siphons when it is contracted; the lobes of the mantle are united up to the gape of the valves and even a little higher; this gaping of the valves as well as the divarication of the lobes of the mantle, gives passage to a great short cylindrical foot, like that of the *Pholades*; but this opening is not at all destined for the passage of the siphons, as Lamarck supposed.

Mr. G. B. Sowerby ('Genera of Recent and Fossil Shells') remarks, that the genera *Pholas*, *Mya*, *Mytilus*, and *Chama*, have by turns served as a receptacle of the shells of this genus. He observes that Lamarck has adopted Spengler's name, but has placed it next to *Pholas*, apparently not having known that the animal forms its own testaceous tube, either as a lining to the hollow it has previously perforated, or as a covering for its shell in those instances in which it has not perforated at all, but in which it has taken up its abode, as it frequently does, within some spiral univalve. Mr. Sowerby is further of opinion, that the fact of the shell being inclosed in a testaceous tube of its own depositing, renders it proper to remove it into Lamarck's family of *Tubicolæ*, to which indeed it appears to Mr. Sowerby to be more nearly related, though he notices a very considerable analogy between the shelly tube of Lamarck's *Tubicolæ*, and the coriaceous epidermis, which not only in a great measure covers the shell, but also incloses the tubes of the animal of Lamarck's *Pholadaceæ*, and Mr. Sowerby consequently thinks that the two families might very properly be united.

Professor Owen, in his paper on *Clavagella*, remarks how closely that form follows the modifications which have been observed in *Gastrochæna*. [CLAVAGELLA.]

Cuvier says that it appears that the *Gastrochænæ* constantly have a calcareous tube, and quotes Dr. Turton, M. Deshayes, and M. Audouin, as having observed it.

M. Rang says that all the *Gastrochænæ* have not a calcareous tube, though all of them burrow in stones after the manner of *Pholades*. If this is to be taken literally, it does not exactly accord with the fact; for sometimes the animal does not burrow at all, at others (and very frequently) it burrows in madrepores. M. Rang adds that two of the species which belonged to the genus *Fistulana* of Lamarck are now arranged in this, and that this arrangement is due to M. de Blainville. These two species, he says, are *Fistulana clava* and *F. ampullaria*. Of these, *Fistulana clava* is referred among the synonyms to *Gastrochæna* by Lamarck, and *Fistulana ampullaria* is declared by M. Deshayes to be a true *Fistulana*, but remarkable in this, that, according to circumstances, it forms a free tube sunk in the sand, or perforates calcareous bodies, and its tube serves as a lining to the cavity which it inhabits; this species therefore, he observes, would belong to the *Fistulanæ* in the first case, and to the genus *Gastrochæna* in the second, if indeed that genus be preserved.

M. Rang states that M. Charles Des Moulins, who a long time ago, and before the observations made upon this subject, had discovered the existence of a tube in the *Gastrochænæ*, had shown him this tube, not only in the living species on the French coast, but in the fossil at Merignac. Following De Blainville, M. Rang would divide the genus *Gastrochæna* into the two following groups:—

α. Species whose shell is smooth and without a distinct tube.
Example, *Gastrochæna cuneiformis*, &c.

β. Species whose shell is striated from the umbo to the base, and contained in a distinct tube.
Example, *Gastrochæna clava*.

M. de Blainville states that the animal of *Gastrochæna* has evidently the greatest relationship to that of *Saxicava*; but as it is not entirely contained in its shell, it often supplies the deficiency by forming an artificial tube adhering to the walls of the cavity which it inhabits in calcareous stones.

This tube, in the opinion of M. de Blainville, offers only an accidental character, and would thus make of species, or even of individuals which are provided with it, *Fistulanæ* of Lamarck. Thus, he observes, M. Deshayes has proposed to suppress the genus *Gastrochæna*, but he would consider it more convenient not to admit the genus *Fistulana*; first, because it is founded upon the presence of a tube; and secondly, because it was established some time after *Gastrochæna*. He would however prefer its restriction as he has restricted it in his 'Malacologie.' In uniting the species characterised by the true shell, whether it have an external tube or not, there exist already, he remarks, many species of known *Gastrochænæ*, both living in the seas of warm climates and fossil in his country. M. Defrance, he states, nevertheless quotes one fossil species only at Grignon, and an analogue; and he concludes by observing that *Gastrochæna clava* would perhaps, if it were better known, form a small distinct genus.

Mr. G. B. Sowerby ('Zool. Proc.,' 1834) describes five new species brought home by Mr. Cuming from South America and the Gallapagos Islands and Lord Hood's Islands.

The following is M. Rang's definition of the genus:—

Animal oval, having the mantle closed with a very small anterior rounded opening for the passage of a small, conical, or linguiform foot: the tubes elongated and united throughout.

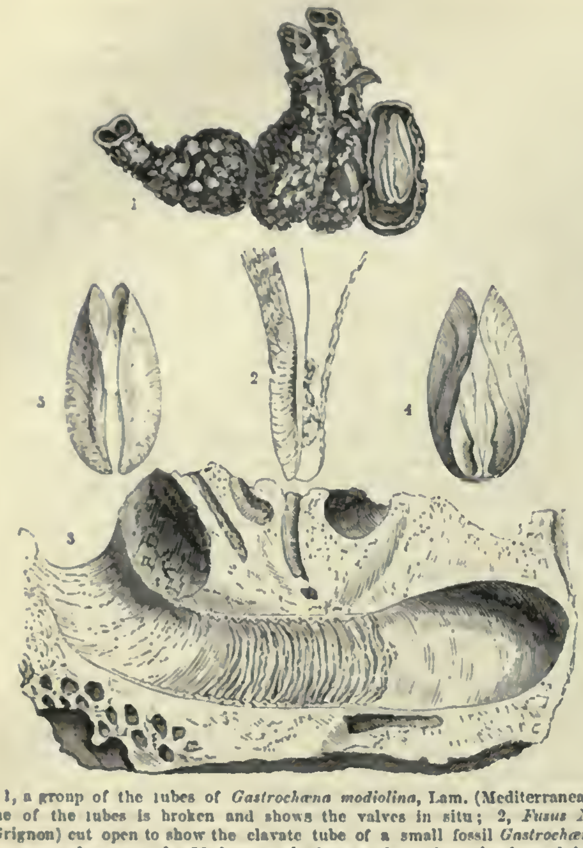
Shell delicate, oblique, oval, cuneiform, equivalve, very inequilateral, gaping extremely at its antero-inferior part; umbones well marked; hinge straight and linear, without teeth; an apophysis often showing itself below the hinge in the interior of each valve; ligament external; muscular impressions distinct, connected by a slightly marked pallial impression excavated posteriorly.

Sometimes a calcareous tube, ampulliform, short, with a rounded aperture, enveloping the shell and lining the cavity of the stone.

G. modiolina has been found on the English and Irish coasts. It is a common inhabitant of the Mediterranean.

Messrs. Forbes and Hanley adopt *Gastrochæna* as the type of a family, *Gastrochænidæ*, in which they include with M. Deshayes not only the genera *Aspergillum*, *Clavagella*, and *Gastrochæna*, but also *Saxicava*; and express the opinion that *Petricola*, and probably *Venerupis*, have strong claims to a similar position. The following is the definition given of this family in Forbes and Hanley's 'British Mollusca':—

"The animals of this amily are oblong or claviform, and often provided with very long siphons, united almost to their extremities, where their orifices are ornamented with cirrhi. The mantle is closed in front, except a small opening for the passage of a very small digitiform foot, very different from that of the *Pholas* tribe. The margin of the mantle around this opening is plain. The shell is equivalve, and often gaping, with valves often very inequilateral, united by a simple rudiment, or in some cases a toothed hinge, often variable, even in the species of a single genus. They have no spoon-shaped apophysis under the beaks, nor accessory plates behind them. A calcareous tube sometimes protects the valves, and in certain genera



1, a group of the tubes of *Gastrochæna modiolina*, Lam. (Mediterranean); one of the tubes is broken and shows the valves in situ; 2, *Fusus Noæ* (Grignon) cut open to show the clavate tube of a small fossil *Gastrochæna*; 3, a worn fragment of a Madrepore, broken to show the tube formed by a specimen of *Gastrochæna cuneiformis*, Lam.; 4 and 5, two views of the two valves of the last-mentioned species. (From the 'Genera of Recent and Fossil Shells,' by G. B. Sowerby.)

unites with them. These tubes are very regular and curious in some of the exotic species, especially in those which live buried in sand. This habit is not merely the living habitually and freely in sand, as the Razor-Fish do, but rather the treating of it in the manner of a substance bored into; and the tubes are to be regarded as the linings of the perforations so made. All the species of the family are borers, most of them preferring calcareous rock."

For an account of *Saxicava* see LITHOPHAGIDÆ.

GASTROCHÆNIDÆ. [GASTROCHÆNA.]

GASTROMARGAS. [QUADRUMANA.]

GAULT. [CHALK FORMATION.]

GAULTHERIA, a genus of Plants belonging to the natural order *Ericaceæ*. It has a 5-cleft or 5-toothed calyx, bibracteate at the base, after flowering becoming large and succulent, and covering the capsule with a baccate coating. The corolla is ovate, ventricose, with a 5-cleft revolute border, transparent at the base. There are 10 stamens, inclosed, with flat filaments; anthers bifid at the apex; lobes biaristate. The hypogynous scales 10, usually united at the base. The ovarium half inferior. The capsule 5-celled, with a loculicidal dehiscence.

G. procumbens, Partridge-Berry, Chequer-Berry, Boxberry, Mountain-Tea, is found on sterile sand and gravel in mountainous forests in the driest situations in North America. It has a horizontal woody rhizoma, often a quarter of an inch in thickness. The branches are ascending, but a few inches high, round and somewhat downy. The leaves are scattered near the extremities of the branches, evergreen, coriaceous, shining, oval or obovate, acute at both ends, revolute at the edge, and furnished with a few small serratures, each terminating in a bristle. The flowers are axillary, drooping, on round downy stalks. There are two concave heart-shaped bracts. The calyx is white, cleft into 5 roundish acute segments. The corolla is white, urceolate, 5-angled, contracted at the mouth, the limb divided into 5 short reflexed segments. The filaments white, hairy, bent in a semicircular manner to accomodate themselves to the cavity between the corolla and ovary. The anthers oblong, orange-coloured, ending in two double horns, bursting outwardly for their whole length. Above the filaments the pollen white. The ovary is roundish, depressed, 5-angled, resting on a reddish 10-toothed glandular disc; the style erect, straight; the stigma simple. The fruit is a small 5-celled many-seeded capsule, invested with the calyx, which becomes large, round, and fleshy, having the appearance of a bright scarlet berry. The fruit contains an aromatic sweet highly pungent volatile oil, which is antispasmodic and diuretic. A tincture has been useful in diarrhœa. Cox states that the infusion is useful in asthma. It is used in North America as tea, and brandy in which the fruit has been steeped is taken in small quantities, in the same way as common bitters. The oil is known under the name of Oil of Wintergreen, and is used by druggists to flavour syrups, and also by perfumers.

G. Shallon is a native of North America on the falls of the Columbia, and near the Western Ocean. It has a procumbent hairy stem, ovate subcordate serrated leaves, glabrous on both surfaces, the racemes secund bracteate, clothed with rusty down. The corolla is white tinged with red, downy, urceolate, with a closed limb. The berries are globose, acute, fleshy, and purple. This plant grows in the shade of close pine-forests where hardly anything else will grow, which makes it a very desirable shrub for plantations. The berries are much esteemed by the natives on account of their agreeable flavour.

G. hispida, Wax-Cluster, is a native of Van Diemen's Land; it has long lanceolate serrulated leaves, piloso beneath as well as on the petioles; the branchlets hispid; racemes axillary and terminal, shorter than the leaves; the rachis and pedicels downy; the calyxes baccate, fruit and ovaries glabrous, the stem erect. It bears snow-white berries, with a flavour by no means unpleasant; in taste it is said to resemble the gooseberry, but is somewhat bitter. According to some *G. antipoda* is said to have more merit as a fruit.

The species are all ornamental, and grow best in a peat soil.

(Lindley, *Flora Medica*; Lindley, *Vegetable Kingdom*; Don, *Dichlamydeous Plants*.)

GAVIAL. [CROCODILIDÆ.]

GAYAL. [BOVIDÆ.]

GAY-LUSSITE, a Mineral, occurring in oblong crystals in a lake in Maricaibo, South America. It is a hydrous compound of the carbonates of lime and soda. (Dana, *Mineralogy*.)

GAZELLE. [ANTILOPEÆ.]

GEBIA. [THALASSINIANS.]

GECARCI'NUS (Leach), the name of a genus of Brachyurous Decapod *Crustacea*, known familiarly to the English as Land-Crabs, and to the French by the appellations of Tourlouroux, Crabes Peintes, or Crabes Violets, some of these terms being applicable not only to different species, but to the same species at different ages, so that those various names cannot be depended upon as specific designations.

Latreille placed this tribe of crabs immediately after Pinnothères. He seems to admit *Plagusia* and *Grapsus* into the same section with the Land-Crabs, properly so called; and next to *Grapsus* come the *Orbiculata* (his fourth section), containing *Corystes*, &c.

Desmarest places *Gecarcinus* at the head of the Quadrilatères of Latreille, and arranges all the true Land-Crabs under that generic title, which is preceded by *Pilumnus*, and succeeded by the *Orbiculata* of Latreille.

M. Milne-Edwards makes the Gecarcinians the second tribe of his family of Catametopes; and in his arrangement they stand between the Thelpusians, the first tribe, and the Pinnotherians, the second tribe of that family.

According to the last-named author the tribe of Gecarcinians is one of the most remarkable groups of the class *Crustacea*; for it is composed of animals breathing by means of branchiæ, or gills, and yet essentially terrestrial, so much so indeed, that they would perish from asphyxia if submerged for any length of time. They may be distinguished easily from the rest of the family by their nearly oval carapace, which is much elevated and convex above. The branchial regions are in general very distinct, and project much below, occupying nearly two-thirds of the surface. The front is very nearly as large as the buccal frame (cadre buccal), and strongly curved below. The orbits are suboval, moderate, and very deep. The lateral borders of the carapace are very much arched, and generally describe a semicircle. The internal antennæ are lodged under the front, and fold back transversely in narrow and often nearly linear excavations. The disposition of the external antennæ varies, and so do the jaw-feet (pates-mâchoires); sometimes the fourth joint is inserted at the external angle of the preceding, and remains exposed, as in the Ocypodians, and sometimes it is entirely hidden under its internal surface. The feet of the first pair are long and strong; the succeeding feet are robust and long, and very nearly equal in size, and their tarsus is pointed and quadrilateral. The abdomen of the male is received in a deep excavation of the sternal plastron, and its second articulation reaches nearly always to the base of the posterior feet. It is in general so long that it comes up to the base of the mouth, and the appendages hidden beneath it are remarkably large. The branchiæ are generally seven in number, namely, five fixed to the vault of the sides, and two, in a rudimentary state, hidden under the base of the preceding, and taking their origin from the jaw-feet; but in some species there are nine on each side. The respiratory cavity is very large, and is raised into a vault highly elevated above the branchiæ, so that above those organs there is a large empty space. The tegumentary membrane with which it is lined is also very spongy, and sometimes forms a fold along the lower edge of the cavity, so as to form a kind of gutter, or longitudinal trough for containing water when the animal remains exposed to the air. (Milne-Edwards.) Observations on this curious reservoir were communicated to the Royal Academy of Sciences in France by Messrs.

Audouin and Milne-Edwards some years ago, wherein the authors show that in all the *Crustacea* the branchiæ are fitted to perform the functions of respiratory organs in the air as well as in the water; that the more or less rapid death of the aquatic species, when exposed to the air, depends upon various causes, of which one of the most direct is the evaporation from the branchiæ, which produces their desiccation; that consequently one of the conditions necessary to the support of life in animals which have branchiæ, and live in the air, is the having these organs defended against desiccation; and lastly, that these dispositions actually occur in the Land-Crabs, which all possess various organs destined for absorbing and keeping in reserve the quantity of moisture necessary for maintaining a suitable degree of moisture in the branchiæ. [CRUSTACEA.]

The Land-Crabs, or Gecarcinians, inhabit the warm countries of the New and Old World, and Australasia; but as far as observation has hitherto gone, America and its islands seem to be the places where the form is most highly and most numerously developed. Almost every writer on the Natural History of the countries last mentioned treats largely on the habits of these creatures; and in the works of Rochefort ('Histoire Naturelle des Antilles'), De Feuillée ('Observations faites sur les Côtes d'Amerique'), De Labat ('Nouveau Voyage aux Isles d'Amerique'), Sloane ('Natural History of Jamaica'), Browne ('Civil and Natural History of Jamaica'), Hughes ('Natural History of Barbadoes), Catesby ('Natural History of Carolina'), &c., &c., will be found details more or less ample, and highly interesting, of their manners; though most of the writers do not determine the species sufficiently to enable us to judge of what particular Land-Crab they are writing. All these authors will however well repay the trouble of consulting them.

Latreille sums up what he considers the credible parts of these narratives thus:—"The crabs pass the greatest part of their life on land, hiding themselves in holes, and not coming forth till evening. Some keep about cemeteries. Once a year, when they would lay their eggs, they assemble in numerous bands, and move in the shortest direction to the sea, without caring for any obstacles. After they have finished their deposit they return much weakened. It is said that they block up their burrows during their moult; and while they are undergoing this operation, and are still soft, they are called Boursiers (Purse-Crabs) [BIRGUS], and their flesh is then much esteemed, although it is sometimes poisonous. This quality is attributed to the fruit of the manchineel, of which the people think, falsely perhaps, that the crabs have eaten."

With regard to the alleged want of foundation for the story of the Land-Crabs being sometimes poisonous, in consequence of what they have eaten, there are so many testimonies to the fact, that it will be a fault on the right side to be cautious. Thus Sloane, who praises (as who does not?) their delicacy of taste, says:—"They are thought to be poysonous when they feed on the Mansanilla-tree leaves or fruit, which I suppose may come from some of it sticking to their chaps, or lying undigested in their stomachs, which are not separated before eating." Catesby writes:—"Some are black, some yellow, some red, and others variegated with red, white, and yellow mixed. Some of these, as well as of the fish of this country, are poisonous; of which several people have died, particularly of the black kind: the light-coloured are reckoned best, and when full in flesh are very well tasted. In some of the sugar islands they are eat without danger, and are no small help to the negro slaves, who on many of the islands would fare very ill without them. They feed on vegetables." Hughes, speaking of the 'large white land-crab,' and its feeding on grass, &c., remarks: "They likewise often feed upon manchineel apples, as well as upon the leaves or berries of poison-trees. At such times they are dangerous to be eaten, unless very great care be taken to wash the fat, as well as the other meat on the inside, with lime-juice and water." He says the same in effect of 'the Mulatto Crab.'

M. Milne-Edwards thus gives his summary:—"The greater number ordinarily haunt humid places, and hide themselves in holes which they excavate in the earth, but the localities preferred by them vary with the species. Some live in the low and marshy lands near the sea, others on the wooded hills far from the shore; and at certain epochs, these last quit their habitual dwelling to go to the sea. It is even reported that then these Crustaceans unite in great bands, and thus make very long journeys without suffering themselves to be stopped by any obstacle, and laying waste everything in their route. Their principal food consists of vegetable substances, and they are nocturnal or crepuscular in their habits. It is more particularly in the rainy season that they quit their burrows, and they run with great rapidity. It would appear that it is at the time of laying that they go to the sea and there deposit their eggs, but we know of no decidedly positive observation on this point. During their moult they remain hidden in their burrows." ('Hist. Nat. des Crustacés.')

We select Browne's account of the Black or Mountain Crab (*Cancer ruricola*, Linn.), because he resided many years in the island of Jamaica, and seems to have lost no opportunity of making personal observations:—"These creatures are very numerous in some parts of Jamaica, as well as in the neighbouring islands, and on the coast of the main continent. They are generally of a dark purple colour, but this often varies, and you frequently find them spotted, or entirely of another hue. They live chiefly on dry land, and at a considerable distance from the sea, which however they visit once a year to wash off their spawn, and afterwards return to the woods and higher lands, where they continue for the remaining part of the season; nor do the young ones ever fail to follow them as soon as they are able to crawl. The old crabs generally regain their habitations in the mountains, which are seldom within less than a mile, and not often above three miles from the shore, by the latter end of June, and then provide themselves with convenient burrows, in which they pass the greatest part of the day, going out only at night to feed. In December and January they begin to be in spawn, and are then very fat and delicate, but continue to grow richer until the month of May, which is the season for them to wash off their eggs. They begin to move down in February, and are very much abroad in March and April, which seems to be the time for the impregnation of their eggs, being then frequently found fixed together; but the males about this time begin to lose their flavour and the richness of their juices. The eggs are discharged from the body through two small round holes situated at the sides, and about the middle of the under shell: these are only large enough to admit one at a time; and as they pass they are entangled in the branched capillaments, with which the under side of the apron is copiously supplied, to which they stick by the means of their proper gluten, until the creatures reach the surf, where they wash them all off, and then they begin to return back again to the mountains. It is remarkable that the bag or stomach of this creature changes its juices with the state of the body; and while poor is full of a black, bitter, disagreeable fluid, which diminishes as it fattens, and at length acquires a delicate rich flavour. About the month of July or August the crabs fatten again, and prepare for mouldering, filling up their burrows with dry grass, leaves, and abundance of other materials: when the proper period comes each retires to his hole, shuts up the passage, and remains quite inactive until he gets rid of his old shell and is fully provided with a new one. How long they continue in this state is uncertain; but the shell is observed to burst both at the back and sides to give a passage to the body, and it extracts its limbs from all the other parts gradually afterward. At this time the fish is in the richest state, and covered only with a tender membranous skin, variegated with a multitude of reddish veins, but this hardens gradually after, and becomes soon a perfect shell like the former: it is however remarkable that during this change there are some stony concretions always formed in the bag, which waste and dissolve gradually as the creature forms and perfects its new crust. A wonderful mechanism! This crab runs very fast, and always endeavours to get into some hole or crevice on the approach of danger; nor does it wholly depend on its art and swiftness, for while it retreats it keeps both claws expanded, ready to catch the offender if he should come within its reach, and if it succeeds on these occasions it commonly throws off the claw, which continues to squeeze with incredible force for near a minute after; while he, regardless of the loss, endeavours to make his escape and to gain a more secure or a more lonely covert, contented to renew his limb with his coat at the ensuing change; nor would it grudge to lose many of the others to preserve the trunk entire, though each comes off with more labour and reluctance as their numbers lessen."

Thus much of the habits of the Land-Crabs of the New World. The late Bishop Heber, in his 'Narrative' gives an account of some Land-Crabs in India, living at a great distance from the sea, and obstructed by great obstacles in their passage to it. "The plain of Poonah," writes the bishop, "is very bare of trees, and though there are some gardens immediately around the city, yet as both these and the city itself lie in a small hollow on the banks of the river Moola, they are not sufficiently conspicuous to interrupt the general character of nakedness in the picture, any more than the few young trees and ornamented shrubs with which the bungalows of the cantonment are intermingled. The principal and most pleasing feature is a small insulated hill immediately over the town, with a temple of the goddess Parvati on its summit, and a large tank (which, when I saw it, was nearly dry) at its base. All the grass-land round this tank, and generally through the Deckan, swarms with a small land-crab, which burrows in the ground, and runs with considerable swiftness, even when encumbered with a bundle of food almost as big as itself. This food is grass, or the green stalks of rice, and it is amusing to see them sitting as it were upright, to cut their hay with their sharp pincers, then waddling off with the sheaf to their holes as quickly as their sidelong pace will carry them." Upon this passage Mr. Broderip observes, that when we call to mind the position of Poonah, and read of the neighbouring river and tank, we may feel inclined to ask whether the river or the tank might not be the scene of ovipositing; and, he adds, that it is not improbable that there may be a race of land-crabs appropriated to continental or even insular situations out of reach of the ocean, and that fresh water may be as necessary to their reproduction as sea-water is to the land-crabs of the West Indies. Such a supposition, he thinks, is in unison with the bountiful provisions of nature for the general diffusion of animal life. ('Zool. Journal,' vol. iv.)

Mr. Westwood in his interesting paper 'On the supposed Existence of Metamorphoses in the Crustacea' ('Phil. Trans.,' 1835), notices the abdomens of several female crabs having the interior surface covered with hundreds of eggs or newly-hatched young, which were in the collection of the late Rev. Landsdown Guilding. One of the bottles in which one of these was deposited was labelled by the last-mentioned gentleman, 'Eggs and Young of a Land-Crab not undergoing Metamorphosis.' From this specimen Mr. Westwood obtained eggs, and young crabs evidently just hatched, and others at a rather later stage of their growth. The eggs were of a dark reddish colour, showing through the outer integument the rudimental limbs of a future animal of a paler colour. On removing the thin transparent pellicle which surrounded one of these eggs, the eyes were most conspicuous, the tail was seen extended as a narrow plate, nearly reaching to the eyes, and along its sides lay the large anterior cheliferous and the four following simple pairs of limbs. The existing organs, although perfectly discernible, occupied only a small portion of one side of the egg, its greater part being filled with hardened matter composed of minute molecular grains. The animal was in a sufficiently forward state of development not to allow the least doubt to be entertained as to the nature of these limbs, nor did any organs appear answering to the two large split pairs of natatory organs of *Zoëa*. The branchiæ, in a fleshy and unorganised state, were also found at the base of the legs. The eggs were $1\frac{1}{4}$ lines in diameter.

Mr. Westwood gives in his 'Memoir' figures of the egg, and of the young crab in progressive stages of growth.

As an article of food some of the Land-Crabs, when in season and well nourished, may be considered as combining the qualities of wholesomeness and delicious flavour. We have conversed with men of various tastes who have partaken of this luxurious food, and all agree in describing it as exquisite. Indeed it appears that when simply cooked in its own juices, in its own shell, it requires no condiment but a squeeze of the fragrant lime to make it one of the best of dishes. "When the Black Crab (*Gecarcinus ruricola*) is fat," says Dr. Patrick Browne, "and in a perfect state, it surpasses everything of the sort in flavour and delicacy; and frequently joins a little of the bitter with its native richness, which renders it not only more agreeable in general, but makes it sit extremely easy upon the stomach. They are frequently boiled and served up whole; but are commonly stewed when served up at the more sumptuous tables." Land-Crabs have been brought alive to this country, and have been exhibited in the Zoological Gardens in the Regent's Park, London. The question has been asked why are not these crabs imported for our tables as regularly as turtle? Barrels with grass and other vegetables, such as they are generally kept in, when there is no better convenience, in their native country, would not take much room on the deck of vessels; and if the crabs were collected at the proper time and allowed sufficient moisture, and only sufficient to keep them in health, an ordinary voyage would bring them to us, most probably, in very fair condition.

M. Milne-Edwards separates the Gecarcinians into the following genera:—

Uça (Latreille).—Carapace much wider than it is long, of a suboval shape, and very much elevated; front narrower than in the other Gecarcinians, very much inclined, and nearly semicircular; orbits rather large, and open externally below their external angle; anterior fossettes suboval, small, and separated by a small triangular prolongation from the epistome; the external antenna occupies the orbitary internal canthus; the buccal frame is of a rhomboidal form; the second and third joint of the external jaw-feet are quadrilateral, nearly of the same size, and terminate on the internal side by a straight border; the fourth joint is inserted at the external angle of the preceding, and is applied against its anterior border; the feet present nothing particular, except that the pincers are a little widened at the end and slightly spoon-shaped, and that the tarsi are flattened, not spinous, and nearly of the same form as in *Ocypode*; thoracic branchiæ five; the membrane which lines the vault of the branchial cavity is folded below and within, so as to form at its lower part a sort of gutter or trough. (Milne-Edwards.)

(*Uça una.*)

Uça una (Marcgrave).—M. Milne-Edwards considers this to be the *Cancer Uça* and *Cancer cordatus* of Linnæus, *Cancer cordatus* of Herbst, *Ocypode cordata* of Latreille ('Hist. Nat. des Crust. et Ins.'), and *Uça una* of the same author ('Encyc. Method.'), and *Gecarcinus Uça* of Lamarck. He observes that M. Latreille cites his *Ocypode fossor* as one of the synonyms of *Uça una*, but that he (M. Milne-Edwards) is inclined to believe that it is rather referrible to *Uça lævis*.

The lateral edges of the carapace in this species are furnished with a small projecting and finely-dentilated crest. Pterygostomian regions very granulous. Manus spiny above and within. Feet hairy below, moderate in length; the third pair rather longer than the others. Size, 2 inches (French). The *Uça una* is a native of South America.

Cardisoma (Latreille).—Carapace more elevated and square than in the greater part of the same tribe. Buccal frame in the shape of a long squared figure, with its lateral edges straight. The second joint of the external jaw-feet narrowed anteriorly, and the third, which is a little shorter than the preceding, widening from behind forwards, so that these organs leave between them, in the middle of the buccal apparatus, a wide space with nearly the form of a lozenge; the third joint, which is nearly cordiform, is notched on its anterior border, and gives insertion at its external angle to the fourth joint, which like the succeeding ones always remains exposed. Front very large and nearly straight. Antennary fossettes transversal, and separated by a semicircular and very wide surface. Feet of the third and fourth pairs longest; the tarsi quadrilateral and very spiny. Branchiæ placed under the vault of the sides, seven on each side, the first being ordinarily very small and the last two very long.

The species of this genus live in the woods, and dig deep and oblique holes, whence they come not forth except at night. (Milne-Edwards.)

C. Carnifex. This, according to M. Milne-Edwards, is the *Cancer Carnifex* of Herbst; *Ocypode cordata*, *Gecarcinus Carnifex*, and *Cardisoma Carnifex* of Latreille; and he cites also *Gecarcinus hirtipes* of Lamarck, as a synonym, but with a query.—Carapace very much elevated, and its surface very much curved from before backwards, but nearly horizontal transversely: its lateral edges marked by a projecting and elevated line. A small tooth behind the external orbitary angle. Four rows of spines upon the tarsi; the two lower not numerous. Pincers large on one side. Manus very large. Fingers touching nearly throughout their length. Length, 2 inches (French). (Milne-Edwards.)

It is found in the neighbourhood of Pondicherry.

Cardisoma Carnifex.

Cancer Hydromus of Herbst, in the opinion of M. Milne-Edwards, is evidently a species approximating closely to the preceding, if indeed it can be distinguished from it.

Cardisoma Guanhumi, which inhabits the Antilles, is more than three inches in length, and the claws of the male are larger than the body, very much curved, and not touching except at their extremity.

Gecarcoïdea.—Carapace more oval and less elevated than in the preceding genera. Front of moderate length, straight, and very much inclined. Antennary fossettes rounded, and separated by a small triangular prolongation of the front. Orbits small; their inferior border much less projecting than in the preceding genera, and leaving between its internal angle and the external antenna a large and deep notch. Buccal frame not so clearly circumscribed as ordinarily, and rather circular than square. External jaw-feet with a wide space between them; their third joint much less than the second, nearly quadrilateral, little or not at all narrowed backwards, and deeply notched at its anterior edge, at the middle of which is inserted the succeeding joint, which is exposed.

G. Lalandii. Carapace inclining to oval, and without a crest on its lateral edges. Feet strong; pincers large, cylindrical, tuberculous, and touching throughout their length; anterior edge of the arms nodulous; succeeding feet dentilated on the edges, those of the third pair the longest. Six rows of dentations on the tarsi. Colour brownish-red. Length rather more than three inches. (Milne-Edwards.)

It is found in Brazil.

Gecarcinus.—Carapace not much elevated, but very convex on the sides. Front very strongly curved below. Orbits deep, inclining to oval, and without a notch on the external side. Internal antennæ nearly hidden under the front, which has a small prolongation that goes to join the epistome. The disposition of the external antennæ and that of the canthus of the orbit nearly the same as in the preceding genus. Buccal frame nearly circular, and not clearly separated from the pterygostomian regions. External jaw-feet very wide, but with a space between them; their second joint completely covers the succeeding joints, which are inserted on its internal surface. The external appendage of these organs is hidden under their second joint, and its extremity scarcely overpasses it. Feet presenting nothing remarkable, excepting that their edges are armed with spiniform teeth.

It is an inhabitant of the Antilles and Australasia.

G. ruricola; Cancer terrestris, Seba; *Cancer ruricola*, Linnæus; the Land-Crab, Sloane; the Black or Mountain-Crab, Browne; Crabe Violet (?), Labat. Tarsi armed with six rows of spiniform teeth. Internal edge of the third joint of the jaw-feet without any remarkable fissure. Carapace very large. A few teeth on the internal edge of the carpus. Length rather more than three inches. Colour purplish or reddish-violet, or yellow washed with red. (Milne-Edwards.)

It is found in the Antilles.

Land-Crab (*Gecarcinus ruricola*).

Fossil Gecarcinians.—M. Desmarest, in his 'Histoire Naturelle des Crustacés Fossiles,' describes and figures a species which he notices as being sufficiently common in collections under the name of *Gecarcinus trispinosus.* The same author, in his 'Considérations Générales sur la Classe des Crustacés,' alludes to this figure and description; and observes that he has arranged the fossil, with doubt, under the genus *Gecarcinus.* M. Milne-Edwards ('Histoire Naturelle des Crustacés') expresses his belief that this fossil is not a Gecarcinian; and says that it would appear, from the form of the carapace, to approximate more to the genus *Pseudograpsus.*

GECKO'TIDÆ, a natural family of Saurian Reptiles, belonging to Gray's sub-order *Pachyglossa*, and the tribe *Nyctisaura.*

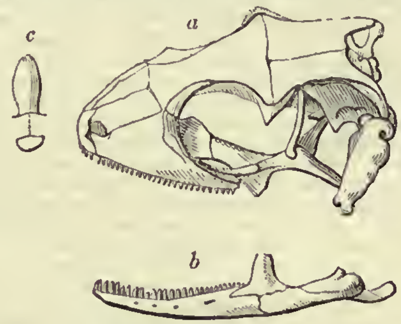
Their head is wide and flattened, with the mouth wide; the nostrils are distinct and lateral; the eyes large, hardly surrounded by short lids, the lower edge of which in the greater number of species does not project outwards, the pupil sometimes rounded, but most frequently dentilated, linear, and lightly fringed; and the auditory opening bordered with two folds of the skin. The teeth are small, equal, compressed, sharp at the point, entire, and planted in the internal edge of the jaws: there are none on the palate. The tongue is short, fleshy, capable of but little elongation, and free at its extremity, which is either rounded or flattened, or very slightly notched.

Their neck is apparently little, in consequence of the width of the back part of the head and the squareness of the shoulders. Their body is thick and short, depressed, and low on the legs, with a belly flat below, dragging on the ground, and largest in the middle. There is no crest on the back. The tail varies, but is not long, and often has folds or circular depressions, but never a dorsal crest.

The feet are short, nearly equal in length, wide apart, and robust; the toes nearly equally long, most frequently flattened below, widened, and furnished with transverse imbricated plates; the nails vary, but they are ordinarily hooked, sharp, and retractile. The conformation of the feet enables the Geckos to run with ease on the smoothest surfaces in every direction, or to remain stationary on them with the back downwards, after the manner of a common house-fly.

The skin is defended by equal granular scales, most frequently interspersed with other tubercular scales, the points blunt or angular. There are femoral pores, or pores in front of the vent, on the same line in the majority of species, and most frequently in the males only. The limbs and sides are sometimes bordered with fringed membranes.

Skeleton.—The skull of the *Geckotidæ* is marked by some peculiar characters. The bones are well defined, nor do the sutures seem to be obliterated by age. In general contour it approaches the skull of the *Crocodilidæ* by its width, its flatness, and its length; its particular resemblances to the same part in that family are to be found in the disposition of the orbits and in the articulation of the jaws. The excavations for the eyes are very large and apparently incomplete, inasmuch as the orbital frame is not entirely bony in its back part, nor has it, so to speak, any flooring, so that when deprived of the softer parts the cavity communicates with the mouth. The articulation of the jaw is quite backwards, and the os quadratum or interarticular bone is wide, short, and hollowed on its posterior surface, for the purpose of receiving the muscle, whose office it is to open the jaws and keep them open. The skull differs from that of the other lizards generally in the extreme smallness of the jugal and temporal bones, and in having the parietal bones divided longitudinally into two.



Skull of a species of *Gecko.*
a, cranium; *b*, lower jaw; *c*, a tooth enlarged. (Cuv., 'Oss. Foss.')

The vertebræ vary in number, and, according to Meckel, their body is hollowed into two conical cavities, very nearly like those of fishes: the spinal column is without any spinous processes or projections. The first three or four cervical vertebræ only are without false ribs or transverse articulated apophyses. These are gradually developed, and go on increasing in length and curvature to the fifth or seventh, but none of them are actually joined to the great anterior portion of the sternum. Those which follow reach and are articulated with that bone. They are succeeded by the free or abdominal ribs, which nearly equal in number the vertebræ which precede the pelvis, at least in the Banded Gecko.

The sternum in the Common Gecko (*Platydactylus guttatus* of Cuvier; *Gecko verus* of Merrem and Gray), consists of a very solid plate, which receives anteriorly and laterally in two angular notches the coracoid bones, which are wide and delicate, and the clavicles, which are narrow, elongated, and flattened, more especially at their sternal extremity. The rhomboid and backward portion of this sternal plate affords attachment on the two posterior facings to three pairs of ribs. From the posterior or abdominal angle of this bone two small parallel bones or sternal prolongations are given off, along which three other pairs of ribs are affixed by ligaments. After these six pairs of sternal ribs come seven other pairs, which are curved at their free or abdominal extremity into an obtuse angle, so that they are at this end directed forwards without any junction to a mesial line, as in the Chameleons. M. Duméril says that generally he has only counted 17 ribs, but he observes that there are 24 in the Banded Gecko (*Platydactylus vittatus* of Cuvier; *Gecko vittatus* of authors). Hence M. Duméril concludes that the number of ribs varies according to the species.

The caudal and pelvic vertebræ require notice. The articulation of the former is either weak, or the body of the vertebra itself is apt to break in the middle, so that a slight effort separates them, and many individuals consequently lose their tails. When these are regenerated, cartilage is generally found in the place of the former bone, and the tail then presents a variety of forms.

The bones of the limbs do not differ from those of the other Saurians so as to require any particular description, with the exception of those of the feet, and there the difference is striking with relation to the greater portion of the class. In the *Geckotidæ* the bones of the feet are so disposed as to receive the five toes of equal or nearly equal length, and which radiate as it were from a centre so as to form a nearly complete circle; for the external or great toe cannot separate itself from the others to extend itself backwards. The toes are not always furnished with nails; but they are often provided with very remarkable ones, which by their mobility and retractility remind the observer of the organisation of the same parts in the Cats (*Felidæ*).

Muscular System.—The muscles of the *Geckotidæ* are highly irritable, as might be expected in such nimble creatures. Their power of adhering to smooth surfaces makes it necessary that the resistance produced by the adhesion should be instantaneously overcome in case of danger; and we accordingly find that a Gecko which at one moment is fixed motionless to a spot, vanishes as it were in the next from under the hand stretched forth to capture it.

The brain and nervous system are considerably developed in the *Geckotidæ*, and the greater part of the senses are acute.

Sight.—The orbits, as we have seen, are large and without any flooring or base, and as the eye in this family is very large in proportion to the size of the animal, the projection of the posterior part of the globe may be seen in the inside of the mouth much in the same way as is observable in some fishes. There is scarcely any lid, and what there is is so small that an additional appearance of prominence is given to the eyeball. This lid is simple, circular, and adherent to the globe of the eye by an internal fold. There is a nictitating membrane. Most persons have seen that an epidermic scale which seems to be the external layer of the cornea comes off in serpents with the rest of the skin, and in the Geckos also the integument passes over the front of the eyeball. The eye in such animals never appears humid. M. Jules Cloquet has shown that in the serpents the tears probably are diffused between the epidermic scale and cornea in order to arrive at the nostrils. The pupil is sometimes rounded, but most frequently presents a linear slit, the edges of which are fringed, so that the animal can at its pleasure dilate or diminish the opening through which the light and the images are to be admitted to the retina. Like the Cats therefore, the Geckos, though said to be nocturnal in their habits, can also see perfectly well in broad daylight.

Hearing.—The auditory apertures in this family are sometimes in the form of slits, sometimes in that of oval or circular holes, and the edges are often rounded and sometimes dentilated. Wagler states that these apertures can be closed in *Ptyodactylus* and *Spheriodactylus*, and it is extremely probable that the rims have a power of approximation generally. The tympanum lies deep, and the auditory cavity communicates with the back of the mouth or throat for the admission of air, as in most pulmoniferous animals. M. Duméril says, that he has proved the sensibility of these animals to the least noises, and that their sense of hearing is very fine.

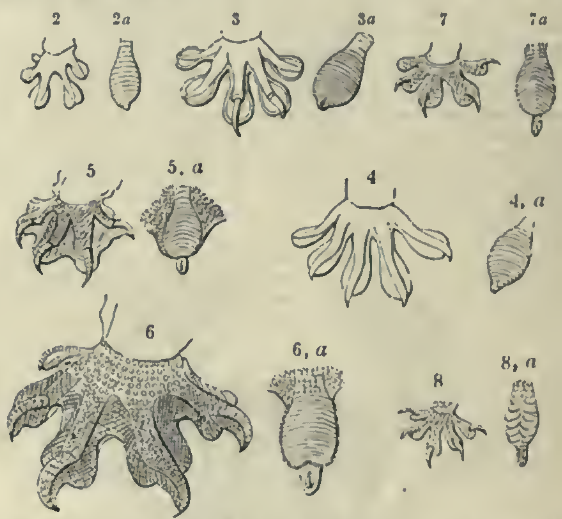
Smell.—The structure of the nostrils in this family would not lead to the conclusion that their sense of smelling is very acute, though it is probably more highly developed than it is in the Frogs.

Taste.—The *Geckotidæ* swallow their prey living, or nearly so, and almost entire, but the presence and form of the teeth render it probable that they can masticate; and this power, combined as it is with the form and structure of the tongue, which is soft, moveable, very fleshy, and furnished with papillæ, seems to indicate a certain degree of the sense of taste.

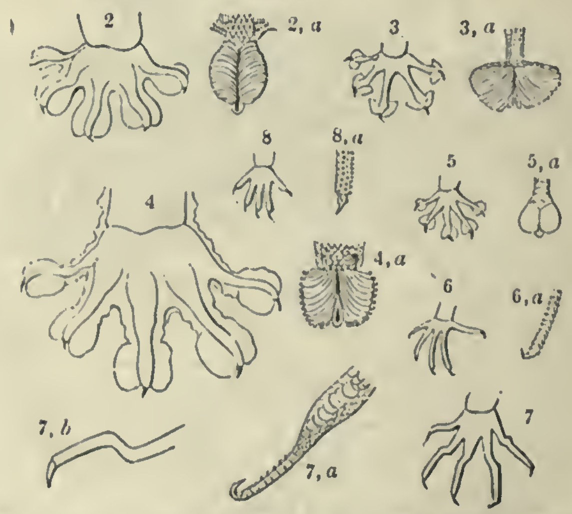
Touch and Integuments.—The skin of the Geckos is generally delicate, and adheres but little to the muscles, from which it is easily detached. In the middle of the back, and sometimes on the sides, granular tubercles rounded on their edges, with others which project at the centre, and are even fashioned into facets, are to be detected in the greater number. When the skin is detached and held up to the light it is seen to be regularly furnished with small delicate rounded escutcheon-like bodies, set in the thickness of the skin. The form and distribution of these bodies vary according to the different species in the regions of the belly, of the neck, of the thighs, of the head, and of the tail. M. Duméril, who gives us this information, goes on to state that generally the skin of the *Geckotidæ* is gray or yellowish, but that there are species in which lively colours are disposed on some parts of their bodies, and that it is even said that tints of red, blue, and yellow may be distinguished, which the animal causes to appear and disappear nearly after the manner of the chameleons. Some travellers assured Wagler that certain Indian Geckos became luminous or phosphorescent during the night.

In some of the species the skin is prolonged on the sides of the body and tail into membranes regularly festooned or fringed, and the Geckos generally moult or change their skins at certain periods of the year, when their colours, as is usual in such cases, become brighter. M. Duméril says that he has himself observed this in living individuals captured in their wild state at Cordova, in Spain, in the middle of the summer. There can be little doubt that there is considerable sensibility where the skin is constructed as it is in the Geckos; but in considering the sense of touch, the curious organisation of the feet and toes demands our particular attention. These are the great organs of station or fixation and progression, and the manner in which they perform their office is very interesting. M. Duméril, after referring to Wagler's reflections on this subject in his remarks on the *Platyglossi*, gives his own observations on this part of the organisation of the Geckos. He refers to the comparative shortness and general structure of the feet above given, and then proceeds to notice the particular conformation of the toes in the greatest number of species. The lower surface of these, and the sole, are very much dilated, widened, and furnished with small plates or lamellæ, following or overlying each other (lamelles placées en recouvrement) in a regular manner, but in a mode which varies in the different species. The nails, which are sometimes wanting on all the toes, are most frequently pointed, hooked, and more or less retractile, constituting a sort of claws, which remain constantly sharp. The toes are sometimes united at their base, and, as it were, semipalmated. In some of the species, *Ptyodactylus* and *Spheriodactylus* of Cuvier, for instance, the extremity of the toes expands, and widens considerably in form of a fan or semi-disc, as in the Tree-Frogs.

The membranous and soft plates with which the lower surface of the toes of the Geckos are furnished present a variety of modifications in the different genera. Sometimes they are simple, or continued from one edge to the other, and those of this class offer distinctions in the furrows themselves, and in the curves described by the lines which mark them; sometimes they are separated longitudinally by a groove; sometimes they are complete or continued throughout the length; sometimes they exist on the last phalanges only; and lastly, in the aberrant genera they are hardly distinct. The modifications of this curious apparatus, as well as the absence or presence of the nails, afford the leading characters on which herpetologists have established the different genera, and we here present the various forms collected by M. Duméril.



Form and structure of the under part of the toes of *Geckotidæ*. The figure marked with the numeral only, represents the foot: the figure marked with the added letter *a*, represents the structure of the lower part of the toe. 2, *Platydactylus Cepedianus*; 3, *Platydactylus Ægyptiacus*; 4, *Platydactylus guttatus* (*Gecko verus*, Common Gecko, of Gray); 5, *Platydactylus homalocephalus* (*Ptychozoon*, of Kuhl; *Pteropleura*, of Gray); 6, *Platydactylus Leachianus* (*Ascalaboles Leachianus*; Griff., 'Anim. King.'); 7, *Hemidactylus Oualensis* (*Peropus*, of Wiegmann); 8, *Hemidactylus triedrus*.



The numerals and letters indicate the same parts as they do in the upper figure, with the exception of 7, *b*, which represents a claw in profile. 2, *Thecodactylus Theconyx*; 3, *Ptyodactylus Hasselquistii* (*P. guttatus*, of Rüppell, House-Gecko, Griff. 'Anim. King.'); 4, *Ptyodactylus fimbriatus* (*Gecko fimbriatus* of authors; Fimbriated Gecko, Griff., 'Anim. King.'); 5, *Phyllodactylus porphyreus*; 6, *Gymnodactylus scaber* (*Stenodactylus scaber* of Rüppell; *Cyrtodactylus*, of Gray?); 7, *Gymnodactylus pulchellus* (*Gonyodactylus pulchellus* of Wagler; *Cyrtodactylus pulchellus*, of Gray); 7, *b* represents a claw of the animal seen in profile.

Digestive System.—The numerous teeth of the Geckos are similar in form and length, placed on the same line, and fixed in a longitudinal furrow on the internal edge of the jaw by the external surface of their roots. The enamelled crowns are cutting, and their base is rounded. From their position in the jaw, Wagler has derived his designation Pleurodonts, the teeth being attached laterally while they are free internally, or in the furrow destined for their reception. In the greater number the crown increases from above downwards. These teeth are so closely set that they seem to touch each other, and altogether form a very trenchant dentilated blade, though not long enough for cutting up substances of any thickness, nor does the bite of the animal inflict a wound.

The œsophagus is very wide, and M. Duméril notices an extraordinary appearance therein, when it is remembered that the part is not exposed to the light. In many species, both living and dead, which he examined, he found the interior of this canal strongly coloured with different but uniform shades, sometimes of an orange-yellow, but principally of a deep black. There is no distinct limit between the œsophagus and the stomach; the crop (jabot) is continuous, and the whole forms a kind of longitudinal sac, which appears to be suddenly narrowed at the point corresponding to the pylorus, which is not to be detected except by this diminution of diameter and its position on the free and lower edge of the liver. The intestine is arranged in sinuous folds, and about three times the length of the œsophagus and ventriculus taken together, it turns to the left, and is lost on the side of a true and large cæcum, furnished with an appendage, and terminating by a large tube which has its opening in the cloaca.

The triangular liver is placed in the mesial line, but its upper angle is so much elongated, that in some species it forms a conical point, at least twice as long as the base. This point lies in front of the stomach in the space left by the two lungs when they are filled with air. Below, the liver enlarges, and is divided into many lobes or indistinct strips, with the exception of that on the left, which is longest. The gall-bladder is situated under the mesial lobe. M. Duméril states that there does not appear to be a pancreas, but he observed in the Common Gecko and in the Fimbriated Gecko (*Ptyodactylus fimbriatus*) a very small spleen situated on the left side of the stomach.

Circulating System.—The shape of the heart varies. In the Common Gecko it is large and flat, but has nevertheless a tolerably regular conical form, the point of the cone being below, and the base, which is slightly notched, leaning on the root of the two lungs. In the Fimbriated Gecko, on the contrary, M. Duméril states the heart to be proportionally smaller, and apparently formed of three distinct but approximated portions, the two upper rounded and oval, resembling auricles, and the other and lower portions small and conical. He acknowledges that he has not followed out the vascular system, but presumes that it resembles in its distribution that of the other Saurians.

Respiratory System, and Organ of Voice.—The glottis consists of a longitudinal slit with two large lips, which form a sort of tubercle behind the posterior notched portion of the tongue, the movements of which it follows, and can consequently be lifted up and applied to the concavity of the palate. The trachea is very large, and the rings, which are cartilaginous anteriorly but membranous on the side next to the œsophagus, cause it to be considerably flattened. The lungs form two sacs, as in the Salamanders, and are nearly equal in volume and length. Their internal cavity is simple, but there are polygonal cellules on their internal membranous linings, and in the lines forming these the arterial and venous vessels are ramified. The *Geckotidæ* are without any goitre, and M. Duméril is unable to account for the production of the voice, but he inquires whether the cry which they emit, and which is supposed to be in some degree imitated by their names of 'Gecko,' 'Geitje,' &c., may not be assisted by the movements of the tongue, and its reception in the concavity of the palate; analogous, we suppose, to the production of the sound with which a coachman or groom stimulates his horses by applying the tongue to the upper part of the mouth and suddenly withdrawing it.

Urinary and Genital Organs.—There is no urinary bladder, nor do the rounded kidneys, whose ureters are not long and open directly into the cloaca, require particular notice. The organs of generation in the males (which are smaller, more agile, and more brightly coloured than the females) are double, and lodged on each side of the base of the tail, which has consequently a swollen appearance. The eggs, which are often deposited between stones, are quite round, with a rather solid, slightly rough, calcareous shell, of a uniform dirty white. M. Duméril has seen these eggs produce the young ones, which were well-formed and very nimble.

The author last named states that he has observed in many species some peculiar organs, sometimes double, sometimes united in a single flattened elongated mass under the abdominal parietes in front of the pubis, in place of a urinary bladder. They appeared to be of a fatty nature, and were sustained in one part by the os pubis, and on the other possessed vascular or membranous single or double prolongations, rising in the thickness of the peritoneum as far as the liver. Though he knows not the office of these organs, he thinks it probable that they may be destined to afford nourishment to the animal in a state of hybernation. The pores of the thighs, &c. secrete a thick humor; and M. Duméril observes that these pores afford no generic character.

The *Geckotidæ* are none of them large in size, and the greatest number feed on small animals, such as insects, their larvæ and pupæ. These they catch either by lying in ambush or by pursuing their feeble prey in the holes and dark crevices to which it retires. The structure of their feet enables them to run in every direction over the smoothest surfaces, and they can even remain suspended beneath the large leaves which a luxuriant tropical vegetation so frequently puts forth. The sharp and retractile nails with which the feet of the greater number are armed, enable them to cling to and make rapid progress on trees with the smoothest bark, to penetrate the holes of rocks, and to climb walls. Of sombre or varying colours adapted generally to the locality where their lot is cast, they will often remain for hours in positions as extraordinary as the flies and insects for which they watch, the wonderful apparatus with which their feet is furnished enabling them to overcome the general law of gravity, and without which they would instantly fall to the earth. The hues of their skins thus render them less objects of suspicion to the little animals for which they lie in wait, and also serve to dodge even the acute eye of the bird of prey that seeks to destroy them. Their eyes, as we have seen, enable them to discern objects in the dark, and are at the same time capable of bearing the rays of a bright sun; for many insects are nocturnal or crepuscular, while the great mass of them are diurnal. The pursuit of their prey leads them near the habitations of man, whose dwelling always attracts certain kinds of insects, and they sometimes fall victims to their appearance, which frequently inspires terror, and often disgust. A Gecko, confident in his powers of flight, appears boldly to await his adversary, and his sudden disappearance at a nearer approach adds to the horror which his uncouth form inspires. The poor Geckos too have a bad name. They are supposed to poison whatsoever they touch, be it animate or inanimate, and their saliva is said to vex the skin of those on whom it falls with foul eruptions. Many of these cuticular irritations, when they have actually existed from the intervention of these animals, may have arisen from the extremely sharp claws of a Gecko running over a sleeping man, or small blisters may have been raised by the adherent apparatus at the bottom of its feet.

The *Geckotidæ* are found in all the four quarters of the globe, and are widely distributed in warm climates. In this distribution, Europe, as far as observation has yet gone, claims by far the fewest number. Two species only have yet been found in this quarter of the globe, and even these are common to the northern coasts of Africa. Prince C. L. Bonaparte has noticed them in the 'Fauna Italica,' under the names of *Ascalabotes Mauritanicus* and *Hemidactylus triedrus*. The former is a *Platydactylus* of Duméril and others.

Systematic Arrangement.—There can be little doubt that the Ἀσκαλαβώτης of Aristotle and of the Greeks generally was a Gecko. Aristophanes and Theophrastus, as Gesner has shown, speak of those lizards which the Italians called Tarentola, whose bodies were short and thick, and which clambered about the walls in the interior of their edifices for the purpose of catching spiders, on which they fed, under the names of *Ascalabotes* and *Galeotes*. That the *Stellio* of Pliny was no other than a Gecko, Schneider has shown.

Linnæus placed the Geckos under his great genus *Lacerta*, and recorded but three species (1766).

Laurenti (1768) seems to have been the first modern who established the Geckos as a genus. Gmelin (1789, 13th edit. of 'Syst. Nat.') introduced a section in the genus *Lacerta*, consisting of five species, under the name of *Gekkones*, and the term Gecko was used as a generic appellation for these Saurians by Lacépède (1790), Schneider (1797), Cuvier (1798), and Brongniart (1801).

Daudin (1803) divided the genus *Gecko* into three sections, taking for the basis of his division the number and connection of the toes, the form of the tail, and the disposition of the scales. These sections consisted of the Geckos properly so called, the Geckottes, and the Geckos with a flat tail. M. Duméril, who has written so much and so well on this subject, and to whose writings we are so much indebted, states that in 1806 he profited by the foregoing works, and established in the 'Zoologie Analytique,' and in his public lectures the genus *Uroplatus* (1806), and he says that Oppel, in his 'Prodromus' (1811), established the family *Geckotidæ* after his (Duméril's) indications. M. Duméril, who established also the genus *Urotornus*, adopts in great measure the system of Cuvier, and separates the *Geckotidæ* into two great divisions, each embracing subdivisions. These divisions take the structure of the toes for their basis; the first consisting of those *Geckotidæ* which have dilated toes, the second of those whose toes are not dilated. The subdivisions depend upon the variation in the structure of the lower part of the toes. The genera are—*Ascalabotes*, *Platydactylus*, *Hemidactylus*, *Ptyodactylus*, *Thecadactylus*, *Stenodactylus*, and *Gymnodactylus* (1836).

Cuvier (1817-1829) placed these Saurians under his great genus *Gecko*, which he divided into the following sub-genera:—*Platydactylus*, *Hemidactylus*, *Thecadactylus*, *Ptyodactylus*, *Sphæriodactylus*; at the same time arranging those Geckos which have retractile claws, but slender or rather not enlarged toes, in three groups, under the names of *Stenodactylus*, *Gymnodactylus*, and *Phyllura*, the latter embracing those with a horizontally-flattened foliated tail.

Merrem (1820) places the Geckos in the first tribe (*Gradientia*) of the class *Pholidoti*. The sub-tribe *Ascalabotes*, according to him, embraces the *Iguanidæ* as well as Geckos.

M. Latreille (1801-1825) seems to have adopted the views and descriptions of Lacépède in the first instance, and not to have gone much beyond a change of nomenclature in the last work published by him.

M. Fitzinger (1826) makes his Ascalabotoïds consist of the genera *Sarrubus, Uroplatus, Ptyodactylus, Hemidactylus, Thecadactylus, Ptychozöon, Platydactylus, Ascalabotes, Stenodactylus*, and *Phyllurus*.

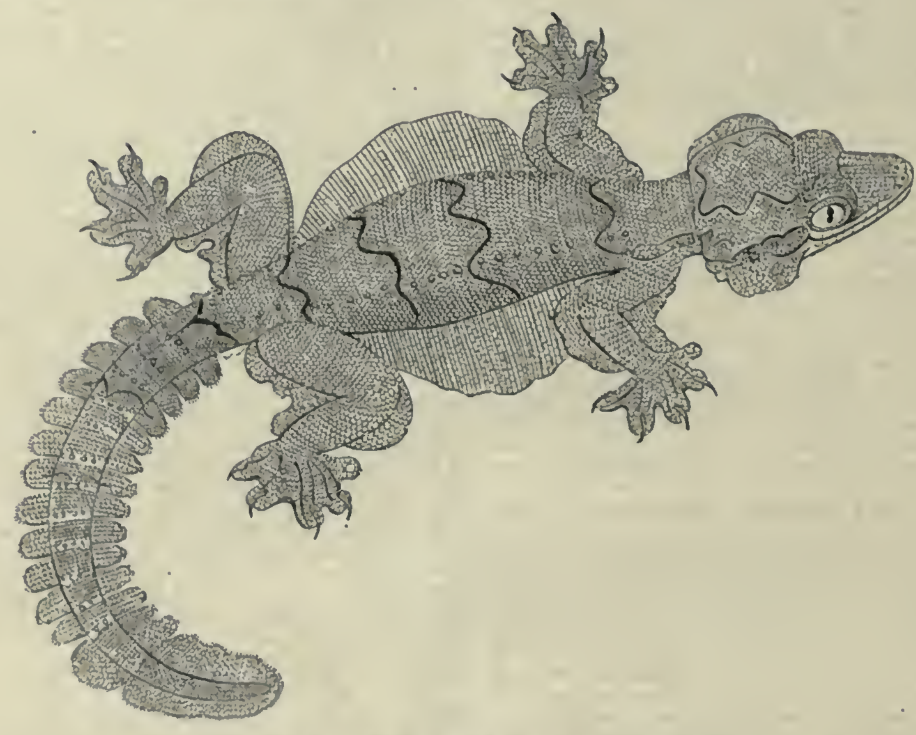
Dr. J. E. Gray (1827-1834) arranges the following genera under the family *Geckotidæ:—Hemidactylus, Platydactylus, Gecko, Pteropleura, Thecadactylus, Ptyodactylus, Phyllurus, Eublepharis, Cyrtodactylus, Phyllodactylus, Diplodactylus*, and *Gehyra*.

Wagler (1830), under the family name of *Platyglossi*, makes the *Geckotidæ* consist of the following genera:—*Ptychozöon* (Kuhl), *Crossurus* (Wagler—*Uroplatus* of Duméril in part), *Rhacöessa* (Wagler—one of Duméril's *Uroplati*), *Thecadactylus* (Cuvier), *Platydactylus* (Cuvier), *Anoplopus* (Wagler), *Hemidactylus* (Cuvier), *Ptyodactylus* (Cuvier), *Sphæriodactylus* (Cuvier), *Ascalabotes* (Lichtenstein), *Eublepharis* (Gray), *Gonyodactylus* (Kuhl), and *Gymnodactylus* (Spix).

Dr. Cocteau (1835) arranges the Geckos into six divisions:—1, *Platydactylus*, containing five subdivisions, represented in part by *Anoplopus* of Wagler, *Phelsuma* (Cocteau), *Pachydactylus* (Wiegmann), *Ptychozöon* (Kuhl), and *Pteropleura* (Gray), with others resting principally upon the absence or presence of pores before the cloaca, and the development of the claws; 2, those Geckos which correspond to *Thecadactylus* of Cuvier; 3, *Hemidactylus*; 4, comprehending *Ptyodactylus* (*Uroplatus*, Duméril; *Rhacöessa*, Wagler; *Crossurus*, Wagler); 5, *Sphæriodactylus*, comprehending *Diplodactylus* (Gray) and *Phyllodactylus* (Gray); 6, *Stenodactylus* (*Eublepharis, Gonyodactylus, Gymnodactylus, Cyrtodactylus, Pristurus, Phyllurus*).

M. de Blainville ('Nouvelles Annales du Muséum,' April, 1836) places the family of Geckos at the head of the family of Saurophians. The species forming the genus *Platydactylus* of Cuvier he designates as Geckos; those ranging under *Hemidactylus* as Demi-Geckos; the *Ptyodactyli* as Tiers-Geckos; the *Stenodactyli* as Quart-Geckos; and the *Gymnodactyli* as Sub-Geckos.

The following cuts will convey an idea of the form of some of the *Geckotidæ*:—



Platydactylus homalocephalus (*Ptychozöon*, Kuhl; *Pteropleura*, Gray).

1, *Platydactylus Seychellensis*. (Duméril.)
1, *a*, the underside of one of its toes.

1. *Gymnodactylus Miliusii* (*Cyrtodactylus Miliusii*, Gray).
1, *a*, the underside of one of its toes. (Duméril.)

The following is a synopsis of the genera and a list of the species, as given in the 'British Mnseum Catalogue,' 1845:—

Synopsis of the Genera of *Geckotidæ*.

I. Toes dilated, with 2 rows of membranaceous plates beneath, under the dilated part.

A. Last joint of the toes short, inflexed, sheathed in the notch between the front of the 2 series of plates. Claws 5-5.

a. Toes dilated, ovate, with 2 series of transverse equal plates beneath.

1. *Thecadactylus.*—Toes half webbed. Femoral pores none. Tail uniformly granular.

b. Toes linear, truncated, middle of the toes with 2 rows of sqnare plates beneath, the 2 terminal plates larger.

2. *Œdura.*—Tail subcylindrical, with square scales, unarmed. Toes all with 2 rows of small plates beneath.
3. *Strophura.*—Tail cylindrical, with 2 rows of spines above, tip revolnte. The 2 middle toes with 2 rows, the rest with 1 row of plates beneath.

c Toes linear, truncated, middle of toes with a single series of plates beneath, 2 terminal plates larger.

4. *Diplodactylus.*—Terminal pair of toe-plates convex, rounded at the end. Back and tail granular, uniform.
5. *Phyllodactylus.*—Terminal pair of toe-plates thin, square at the end. Back and tail tubercular.

d. Toes slender, dilated at the end, with 2 diverging series of plates beneath.

6. *Ptyodactylus.*—Toes free. Body simple. Tail round.
7. *Uroplates.*—Toes webbed. Tail and sides of the head and body fringed.
8. *Caudiverbera.*—Toes webbed. Tail and back with a membranous crest.

B. Toes, last joint slender, compressed, elongate, produced, clawed, free from the dilated penultimate joiuts.

a. Thumb with a compressed clawed termiual joint, like the toes.

9. *Hemidactylus.*—Tail rather depressed, angular above, with cross rings of spines, lower edge simple. Toes free.
10. *Velernesia.*—Tail rather depressed, angular above, with cross rings of spines, lower edge denticulated. Toes half webbed. Skin of sides and limbs lax.
11. *Doryura.*—Tail depressed, uniformly granular, denticulated on the edge. Toes free. Sides and limbs simple.
12. *Platyurus.*—Tail depressed, uniformly granular, denticulated on the edge. Toes half webbed. Sides and limbs with a thin membranous expansion.
13. *Leiurus.*—Tail cylindrical, uniformly grannlar, tapering. Toes slightly webbed. Sides and limbs simple.
14. *Crossurus.*—Tail cylindrical, granular, with a festooned fringe on each side.

b. Thnmb with a compressed, clawless, terminal joint.

15. *Boltalia.*—Toes free.

c. Thumb without any compressed terminal joint, clawless.

16. *Peripia.*—Toes all free.
17. *Peroplus.*—Toes two middle united at their base.

II. Toes more or less dilated, with a single series of transverse plates beneath.

C. Toes dilated, the last joint (only) compressed and rather produced or wanting, the plates beneath the toes membranaceous, smooth.

a. Claws 5-5. Thumb with a compressed, free, clawed last joint.

18. *Theconyx.*—Toes free, dilated. Sides simple.
19. *Pentadactylus.*—Toes free, base slender. Sides simple.
20. *Platydactylus.*—Toes webbed. Sides with a margin.

b. Claws 4-4. Thumb without any compressed, free, clawed, last joint.

21. *Gecko.*—Toes free, last joint short. Back tubercular.
22. *Gehyra.*—Toes free, last joint rather elongate, very compressed. Scales granular.
23. *Amydosaurus.*—Toes half webbed. Back granular. Limbs and body simple.
24. *Lyperosaurus.*—Toes half webbed. Back granular. Hinder edge of legs with a slight fold of thin membrane. Tail with a slight fringe.
25. *Ptychozoon.*—Toes webbed. Head, body, and tail with membranes on the side.

c. Claws 2-2. All but the two middle toes without any compressed last joint.

26. *Tarentola.*—Lower rostral shield very long.

d. Claws none. Toes all without any compressed last joint.

27. *Phelsuma.*—Toes dilated, ovate. Tail rather contracted.
28. *Pachydactylus*—Toes slender, short, apex rather dilated.
29. *Sphærodactylus.*—Toes slender, with a single rounded disc at the tip.

D. Toes and thumbs clawed, slightly dilated below at the base, the two or three last joints compressed, angularly beut, the membranous plates beneath the toes transverse, smooth.

a. Toes rather thick, tapering. Tail round.

30. *Naultinus.*—Tail cylindrical, tapering, granular. Preanal pores in 2 or 3 cross series. Back granular.
31. *Eublepharis.*—Tail cylindrical, ringed with cross series of tubercles. Back tubercular.
32. *Homonota.*—Tail cylindrical, tapering, granular. Preanal pores none. Back scaly.
33. *Pristurus.*—Tail compressed, dentated above.

b. Toes elongate, slender, compressed, versatile, joints bent at angle.

34. *Goniodactylus.*—Tail round, tapering, granular. Scales granular. Preanal pores none.
35. *Cyrtodactylus.*—Tail round, tapering, with rings of tubercles. Back with rows of tubercles. Preanal pores in 2 parallel rows.
36. *Heteronota.*—Tail round, tapering, with rings of tubercles. Back tubercular. Preanal pores in an arched series.

37. *Cubina.*—Tail round, tapering, with rings of tubercles. The back tubercular. Preanal and femoral pores none.
38. *Gymnodactylus.*—Tail rather depressed, tapering, with rings of tubercles. Back tubercular. Preanal pores in a curved series.
39. *Phyllurus.*—Tail depressed, cordate, end round, tapering.

E. Toes and thumbs clawed, cylindrical, tapering, toothed on the side, the plates beneath transverse, many-keeled, denticulated.

40. *Stenodactylus.*

List of the species of *Geckotidæ*, with the Localities they inhabit.

Thecadactylus rapicaudus, the Turnip-Tailed Gecko. Tropical America.
Œdura marmorata, the Marbled Œdura. North Australia.
Œ. rhombifer, the Lozenge-Spotted Œdura. West Australia.
Strophura spinigera, the Strophure.
Diplodactylus vittatus, the Yellow-Crowned Diplodactyle. Australia.
D. ornatus, the Beautiful Diplodactyle.
D. ocellatus, the Eyed Diplodactyle. West Australia.
D. marmoratus, the Marbled Diplodactyle. Australia.
D. bilineatus, the Two-Lined Diplodactyle.
D. lineatus, the Lined Diplodactyle. Cape of Good Hope.
D. Gerhopygus, the Naked Diplodactyle.
Phyllodactylus pulcher, the Phyllodactyle.
P. tuberculatus, the Large-Tubercled Phyllodactyle.
Ptyodactylus Gecko, the Fan-Foot. Egypt.
Uroplates fimbriatus, the Famocantrata. Madagascar.
U. lineatus, the Sharp-Tailed Famocantrata.
Caudiverbera Peruviana, the Caudiverbera. Peru.
Hemidactylus trihedrus, the Triangular-Tubercled Hemidactyle.
H. maculatus, the Spotted Hemidactyle.
H. Brookii, Brooke's Hemidactyle.
H. depressus, the Groove-Tailed Hemidactyle.
H. verruculatus, the Warty Hemidactyle. Shores of the Mediterranean; Egypt.
H. fasciatus, the Banded Hemidactyle.
H. Mabouia, the Brazilian Hemidactyle. Brazil.
H. mercatorius, the Wandering Hemidactyle.
H. frenatus, the Streaked Hemidactyle. Ceylon.
H. Leschenaultii, Leschenault's Hemidactyle. Ceylon.
H. vittatus, the Streaked-Cheeked Hemidactyle. Borneo.
H. Bellii, Bell's Hemidactyle.
H. Peruvianus, Wiegmann's Hemidactyle. Peru.
Velernesia Richardsonii, the Velernesia.
Doryura Bowringii, Bowring's Hemidactyle.
D. Garnotii, Garnot's Doryure. South Sea Islands.
Platyurus Schneiderianus, the Platyure. Java.
Leicerus ornatus, the Banded Leiurus. West Africa.
Crossurus caudiverbera, the Crossurus.
Boltalia sublævis, the Boltalia. India.
Peripia Peronii, Peron's Peripa. Mauritius.
P. variegata, the Variegated Peripa. Australia.
Peropus mutilatus, the Peropus. Manilla.
Theconyx Seychellensis, the Seychelle Gecko. Island of Seychelles.
Pentadactylus Duvaucelii, Duvaucel's Pentadactyle. India; Calcutta.
P. Leachianus, Leach's Gecko.
Gecko verus, the Gecko. India.
G. Reevesii, Reeve's Gecko. China.
G. Chinensis, the Japan Gecko. China and Japan.
G. Monarchus, the Amboyna Gecko. Borneo.
G. Smithii, Dr. A. Smith's Gecko. Prince of Wales Island.
G. vittatus, the Streaked Gecko. Cape of Good Hope.
G. bivittatus, the Double-Streaked Gecko.
Amydosaurus lugubris, the Sombre Gecko.
Gehyra oceanica, the Oceanic Gehyra. Islands in the Pacific.
G. Australis, the Swan River Gehyra. Swan River.
Lyperosaurus Cumingii, the Luperosaure.
Ptychozoon homalocephala, the Fringed Tree-Gecko. Java.
Tarentola Mauritania, the Tarentola. Egypt.
T. Ægyptiaca, the Egyptian Tarentola. Egypt.
T. Delalandii, Laland's Tarentola. Madeira; West Coast of Africa.
T. Americana, the American Tarentola. North America.
T. Borneensis, the Bornean Tarentola. Borneo.
T. clypeata, the Shielded Tarentola. Glasgow.
Phelsuma Cepedianus, Lacépède's Phelsuma. Mauritius.
P. Madagascariensis, the Madagascar Phelsuma. Madagascar.
P. lineatum, the Lined Phelsuma. Madagascar.
Pachydactylus ocellatus, the Eyed Gecko. Cape of Good Hope.
P. maculatus, the Spotted Pachydactyle. South Africa.
P. elegans, the Elegant Pachydactyle. South Africa.
Sphærodactylus sputator, the Banded Sphærodactyle. South America.
S. punctatissimus, the Lined Sphærodactyle. Martinique.
S. fantasticus, the Black-Headed Sphærodactyle. South America.
S. nigropunctatus, the Black-Dotted Sphærodactyle. South America.
S. Richardsonii, Richardson's Sphærodactyle. America.
Naultinus pacificus, the Pacific Naultinus. New Zealand.
N. elegans, the Kakariki. New Zealand.
N. Grayii, the Long-Toed Kakariki. New Zealand.
N. punctatus, the Black-Dotted Kakariki. New Zealand.
Eublepharis Hardwickii, Hardwick's Eublepharis. Penang; Chittagong.
Homonota Guidichaudi, Guidichaud's Scaled Gecko. Chili.
Pristurus flavipunctatus, Ruppell's Pristurus. Abyssinia.
Goniodactylus Timorensis, Boie's Angular-Toed Lizard. India.
G. Australis, the Australian Angular-Toed Lizard. Australia.
G. alboangularis, the White-Throated Angular-Toed Lizard. South America.
G. ocellatus, the Eyed Angular-Toed Lizard. Tobago.
G. Mauritanicus, the Algerine Angular-Toed Lizard.
Cyrtodactylus marmoratus, the Marbled Cyrtodactyle. Java. Philippine Islands.
C. pulchellus, the Beautiful Cyrtodactyle. Singapore.
Heteronota Kendallii, the Bornean Heteronote. Borneo.
H. Binoei, the Australian Heteronote.
Cubina fasciata, the Banded Cubina. Martinique.
C. D'Orbignii, D'Orbigny's Cubina. Chili.
Gymnodactylus Geckoides, the Gymnodactyle. Shores of the Mediterranean.
Phyllurus platurus, White's Phyllure. Australia.
P. Milinsii, the Thick-Tailed Phyllure.
P. inermis, the Spineless Phyllure. Australia.
Stenodactylus guttatus, Wilkinson's Stenodactyle. Egypt.

GEDD. [Esox.]

GEDRITE, a Mineral occurring in crystalline masses having a fibrous radiated or lamellar structure. Its colour is clove-brown. The streak gray or yellowish. The lustre submetallic, feeble. Hardness not above 5. Rough. Specific gravity 3·26. It occurs in loose stones near Gèdre in the Pyrenees. It has some resemblance to Anthophyllite and Hypersthene. It has the following composition:—

Silica	38·811
Alumina	9·309
Protoxide of Iron	45·834
Magnesia	4·130
Lime	0·666
Water	2·301

GEESE. [Ducks.]

GEHLENITE, a Mineral occurring in square prisms. It has a gray colour, and is nearly opaque. The hardness is 5 to 5·6. The specific gravity 2·9 to 3·1. It has the following composition:—

Silica	29·6
Alumina	24·8
Lime	35·3
Protoxide of Iron	6·6
Water	3·3

It fuses with borax with difficulty. It gelatinises with muriatic acid. It comes from the Jassa valley in the Tyrol. (Dana, *Mineralogy.*)

GEHYRA. [Geckotidæ.]

GELA'SIMUS, a genus of Brachyurous Crustaceans. [Ocypodians.]

GELATIN, an animal substance composed of Carbon, Hydrogen, Oxygen, and Nitrogen, found present in all parts of the body, and constituting the walls or external investment of the cells of which animals are composed.

Amongst the component parts of all organised bodies the most frequent is the cell. Modified in an infinite variety of ways, it gives rise to the innumerable varieties exhibited both by plants and animals, in the external form, the structure, and consequently the functions of their organs. In the vegetable kingdom the substance employed in the construction of these cells is cellulose combined with a little protein. In the animal kingdom it is gelatin. The case is very similar, although the elementary form of the tissue and its chemical characters are different. In animals we must distinguish between the persistent and the original cellular substance. The original in all probability varies in different cases, while the persistent exhibits a constant and general character. The persistent tissue is consequently a secondary product, and in this respect differs from the cellular substance in plants, which is a primary or original one; neither has it an actual cellular form like the latter. There is however a resemblance between the two in several points, especially in relation to the large proportions in which they both exist, and to the several functions which they perform.

Gelatigenous substance is so widely diffused over the body that it would exhibit the entire shape of the principal organs, even if all other constituents were separated. It constitutes the skin, the serous membranes, the cellular sheaths of the muscles, the organic portion of bone, and many other substances. It is insoluble in cold water; acetic acid renders it transparent and bulky; tannic acid renders it solid, and prevents its putrefaction; and when boiled it forms a jelly. It is in consequence of the last property that it has received the name of Gelatin. The gelatigenous substance (as in skin, areolar tissue, serous membranes, &c.) is insoluble in cold water, and on boiling is merely physically and not chemically altered. In the process of boiling nothing is taken up and nothing separated; the alteration being similar to that undergone by starch when heated in water.

The composition of Gelatin is represented by the formula—

$$C_{13}\ H_{10}\ N_2\ O_5$$

whether obtained from hartshorn, from isinglass, or from silk. Both boiled and unboiled cellular tissue (after its conversion into glue) combine with tannic acid, and produce compounds which are insoluble in water and resist putrefaction; hence the power of all medicines containing this substance to heighten the tone of the system. The protein-compounds in a similar manner form hard and coherent compounds with tannic acid. Peruvian and willow bark, catechu, and many other astringent medicines produce compounds of this nature in the organism.

On boiling Gelatin in water for a long time we obtain a hydrate of gelatin, which no longer gelatinises: its composition is $4\ (C_{13}\ H_{10}\ N_2\ O_5) + aq.$

This peculiarity should be remembered, for the compound is likely to be formed in the preparation of broth, and in the application of Papin's Digester to cooking; and it is regarded by Mulder as doubtful whether this hydrated gelatin can be again converted in the organism into nutrient matter, and whether it may not produce noxious substances in the body. [FOOD.]

As Gelatin has never yet been discovered in the vegetable kingdom, there is every reason to believe that it is solely produced in the animal body. It is most probably formed from the decomposition of the protein in the blood, through the action of the alkali in the serum, and the oxidising influence of the atmosphere.

We are likewise imperfectly acquainted with the products of the decomposition of the gelatigenous tissues in the body. Out of the body we know that by the influence of oxidation on gelatin prussic acid is formed, and that, by the action of alkalies, gelatin-sugar, leucin, and extractive matters are produced, while ammonia is disengaged, and an alkaline carbonate formed. Finally, when boiled in dilute sulphuric acid, it yields extractive matters with either gelatin-sugar or leucin. Since leucin is also produced from albumen when decomposed by potash, we perceive an intimate connexion between that protein-compound and gelatinous matters.

Besides the gelatin obtained from cellular tissue and serous membranes there is another kind which has many of its properties, but differs from it in composition. It was first described by Müller under the name of Chondrin. It is obtained from the cornea, and from those cartilages which do not ossify by boiling them in water. Its composition is $10\ (C_{32}\ H_{26}\ N_4\ O_{14}) + S$.

Gelatin is extensively employed in the arts in the form of glue, and constitutes the basis of leather. It is found pure in the air-bladder of some fishes, and on being cut up constitutes isinglass. When purified it can be formed into plates of almost glass-like transparency, and when coloured is employed for making artificial flowers and many other ornamental objects. Its relation to the other substances in the animal body are considered under PROTEIN.

GELDER ROSE, or rather, GUELDRES ROSE, a double variety of the *Viburnum Opulus*, a marsh shrub, common in this country and all the north of Europe. The name of this variety is supposed to indicate its origin in the Low Countries: it is also called the Snowball-Tree, in allusion to its large white balls of flowers. [VIBURNUM.]

GELIDIUM. [ALGÆ.]

GEMMASTREA. [MADREPHYLLIŒA.]

GEMMULINA. [FORAMINIFERA.]

GEMS-BOC. [ANTILOPEÆ.]

GENERATIONS, ALTERNATION OF. During the course of the development of many of the lower animals from the ovum to their adult condition, they not only pass through various forms, as is seen in the Insect tribes [INSECTS], but at certain stages of their growth they possess the power of multiplying themselves. The individuals which exhibit this phenomenon have been called 'nurses,' and the whole series of phenomena connected with this mode of reproduction have been called by its first expounder, Professor Steenstrup, an 'alternation of generations.' This phenomenon has been particularly observed in the *Acalephæ*, *Entozoa*, *Polypiferæ*, *Salpæ*, and *Vorticellæ*. In the various articles on these families of animals, their mode of development is described. As however this subject is one of general interest, and very imperfectly understood, we take the opportunity of reproducing here Professor Steenstrup's general remarks on this subject, from a translation of his work published by the Ray Society:—

"The mode of development by means of 'nurses,' or intermediate generations, is thus seen to be no longer an isolated phenomenon in nature. The circumstance of an animal giving birth to a progeny permanently dissimilar to its parent, but which itself produces a new generation, which either itself or in its offspring returns to the form of the parent animal, is a phenomenon not confined to a single class or series of animals; the vertebrate class is the only one in which it has not yet been observed. It would consequently appear that there is something intrinsic in this mode of development, and that it occurs as it were with a certain necessity; on which account it will undoubtedly soon be recognised to a greater extent and more generally. It should no longer be considered as something paradoxical or anomalous (as we have hitherto been too much inclined to deem both it and the phenomena in which it is exhibited), it must be in harmony with the rest of development in nature, in which the fundamental principle of this course of development must also be elsewhere expressed, although it may be displayed in a form under which we shall less readily perceive and recognise it. This is seen when we trace the mode of development in question more widely through nature; and whilst contemplating it through the phenomena in which it is manifested, we comprehend it in its true light.

"If we collect and regard in one view the whole system of development by means of 'nursing' generations, as it is exhibited in the Bell-Shaped *Polypes* (*Campanularia*), the Claviform *Polypes* (*Coryne*), *Medusæ*, *Salpæ*, *Vorticellæ*, and *Entozoa*, it appears as a peculiar and consequently as an essential feature in this course of development, that the species (that is, the species in its development) is not wholly represented in the solitary, full-grown, fertile individuals of both sexes, nor in their development; but that to complete this representation, supplementary individuals, as it were, of one or of several precedent generations are requisite. Thus, the distinction between this course of development and that which is generally recognised in nature, in which the species is represented by the individual (of both sexes) and its development, is the want on the part of the individuals of a complete individuality as representatives of the species, or of a specific individuality, if I may so express it. If now we agree to regard such an incompleteness in the individual as the essence of this development, we shall comprehend its significance in nature when we thoroughly consider this course of development in its various periods, throughout the above-mentioned families, how it begins and advances, so that at last we discover to what it tends. I believe, also, that we might trace even now this development by means of precedent, preparatory generations of 'nurses' in its peculiar course and advance, notwithstanding the paucity of instances adduced in the foregoing pages, and the many gaps in the series of observations. Thus we see the greatest incompleteness and the highest degree of mutual dependence in the *Campanulariæ* and similar *Polypes*, in which the generations representing the unity of the species are very unlike each other, and in which all the individuals are fused, as it were, into an outward unity, or into a set of *Polypes*. They exist, organically connected with each other, and are normally free only in their first generation, and indeed only in their earliest stage of development, and only for a short time, since the free-swimming ciliated embryo swims about in the water at most for some hours, in order to find a suitable place for the foundation of a new polype stem. In the *Corynæ*, or claviform *Polypes*, the organic connection between the individuals and generations is rather more lax; the perfect gemmiparous or ovigerous individuals are usually quite free, often even at an early age (*Coryne fritillaria*, *Corymorpha*), so that they do not attain their full development until after their separation from the 'nursing' generation. In the *Medusæ* and *Salpæ*, the generations which are connected together into one whole, become more like each other; the first generation of the *Medusæ* is still fixed but more active and mobile in its parts; the individuals of the perfect generation leave the 'nursing' animal while still very small, and undergo remarkable changes after they have become free and are swimming freely about; both generations of the *Salpæ*, finally, are free, and free swimmers, only the individuals of one of them are organically connected with each other; they have however no common organs (in the full-grown state), and if my explanation of the alternate generation of the compound Ascidians is correct, we have in that instance precisely the development of the *Salpæ* at a somewhat lower stage; the individuals of the one generation are organically connected, without having a common organ; but both generations are fixed.

"In the class of *Entozoa* a similar progressive attempt at becoming free and accomplishing a perfect growth appears evident to me.

"In the *Cestoidea* the generation of perfect individuals, constitutes externally a unity; they are only successively detached from each other as the term of their existence approaches, and their whole existence is throughout connected with the 'nursing' animal. In some of the *Trematoda*, the later generations remain within the earlier until they have attained their full development; in others they forsake them in an earlier condition, are free, and free swimming, and undergo a complete metamorphosis; in some of these latter, the earlier generations are transformed into motionless, and, as it were, lifeless cysts, whilst in others they remain free and active (the 'nurses' and 'parent nurses' of *Cercaria ephemera* and *C. echinata*), but retain during their whole life a form which, at most, resembles the larvæ of the more perfect generation. In this way an advance in a certain direction may indisputably be observed. At first all the generations constitute a unity, not merely as regards the interior, but also with respect to the exterior: they form a stationary colony; after which the generations are detached more and more from each other, and become at the same time more free; and, finally, all the individuals constituting the generation are separate from each other, and acquire the power of free locomotion. In this latter stage, or that of freedom and perfection, we found the development of animals which are certainly no longer attached to inanimate objects at the bottom of the sea, but live buried in other animal organisms, and belong not to the sea but to fresh water. In a still higher and more free stage than this we observe the development of animals which do not belong to the water, but to the air, as in that which occurs in the *Aphides*. The propagation of these creatures through a series of generations has been already long known. In the spring, for instance, a generation is produced from the ova, which grows and is metamorphosed, and without previous fertilisation gives birth to a new generation, and this again to a third, and so on, for ten or twelve weeks; so that in certain species even as many as nine such preliminary generations will have been observed; but at last there always occurs a generation consisting of males and females, the former of which, after their metamorphosis, are usually winged; fertilisation and the depositing of eggs takes place, and the long series of generations recommences in the next year, and in the same order. All the individuals are free, and enjoy the power of free locomotion, and undergo a metamorphosis. Here, however, we have before us aerial animals, and which are no longer parasites inhabiting other organisms; at most they are only externally parasitic, and on plants alone; the phenomena of this mode of development are no longer exhibited by *Entozoa*, but by *Epiphyta*. Nevertheless, the course of development is in itself similar; but in the external, more free, and nobler form in which it is now exhibited, the endeavour to attain something higher is manifest. Each link or generation certainly brings its offspring nearer to the perfection aimed at; but this approachment towards perfection is effected only by means of the 'nursing' by special animals, and is committed to the still and quiet activity of an organ, without the nursing animals themselves being conscious of it; it is a function merely, and not an expression of the will. In all parts of the animal kingdom we see instances of the still, quiet, and unconscious activity of the animal being developed into voluntary actions, which are undertaken by it from an internal, obscure, and irresistible impulse (or artificial impulse), as is the case in this instance. The development and mode of feeding or nourishing the young, exhibited in its course, of Bees, Wasps, Ants, and *Termites*, affords a direct example of the mode in which the care of the young is provided for, by the voluntary action of numerous individuals devoted to that object. Those of the young which are to be developed into the more perfect, fertile individuals are not protected in the body of the foster-parents, nor is their nourishment secreted by one of the organs; both protection and food are afforded them by means which are brought about by the conscious activity of the 'feeders.' The Wasp, for instance, or the Wild Humble-Bee, which has been impregnated in the autumn, and has afterwards sought a shelter to protect itself against the cold of winter, prepares a solitary habitation in which it builds cells and deposits its eggs. From the eggs proceed larvæ, but the insects into which these larvæ are metamorphosed, are not fertile; they are barren, and all their faculties are directed to the assisting of the parent animal in the better nourishing of the future brood, to which end some of their external organs are transformed, and to the erection of a better habitation and cells, into which they convey the eggs of the female, and the food of the larvæ to be developed from them. Other cells, which contain a better sort of food, are erected for a later and less numerous progeny of eggs; and again in others, which are more roomy and provided with the best kind of food, but of which there are only a few, is the last brood of the female deposited. From the first kind of cells proceed the barren individuals, from the second the males, and from the third the females; after undergoing a metamorphosis, the males and females fly away, impregnation takes place, and the males die; the females however return, and the whole multitude of barren individuals, which at the same time perform the duty of feeding the young, build cells for their various progeny of eggs, and nourish the three forms of larvæ which proceed from them. In this way the inhabitants of the colony become very numerous; nevertheless they all die off in the winter: the fertile females alone remain alive, and propagate the species the year following, under the same development of alternating broods, the earlier of which is always by far the most numerous, and assists in the development of the latter. In the colonies of Bees, Ants, and *Termites*, the same thing occurs; the many thousand individuals which constitute one of these colonies are principally 'feeders,' or individuals which have originated in the precedent divisions of the eggs of the females, and in these is exhibited, even with greater precision, a more marked division of labour in the feeding of the progeny; so that, out of the various precedent divisions, individuals apparently arise which assist in the development of the more perfect progeny in various ways. Thus there are in a hive of bees, individuals which are employed almost wholly in the feeding of the larvæ (foragers), whilst others do scarcely anything else than collect wax and build cells (workers). In ant-hills, one set of the feeders is constantly employed in conveying the larvæ from one place to another, according as they require a greater or less degree of warmth, &c., whilst others are engaged in building the passages or earth-cells, and in making excavations around the habitation. Among the *Termites* also we are acquainted with several forms of 'feeders,' constituting particular tribes or classes; the description of labour, however, which each of these classes performs, is unknown. It is known, however, that a form with a large head and strong jaws is always posted at the entrance of the artificially constructed dwelling, and keeps guard there as soon as any disturbance is remarked, and thus constitutes the safeguard not only of the young but of the whole community.

"Now in the cases in which the more perfect development of the progeny is promoted, either by means of 'nurses' or of 'feeders' (under which latter term we understand special individuals devoted to the actual care or nourishing of the young, which office they fulfil by a conscious activity), we see that nature always has in view the production of a multitude of individuals to whose life or care is then committed the perfecting of a later generation or progeny, consisting of less numerous individuals. This previous or preparatory multitude seems to consist invariably of females, the males being apparently excluded from any participation in the office, on which account the males of all the animals among which the system of 'nursing' or of 'feeding' obtains, constitute a very subordinate number. That the 'nursing' should be committed to females alone appears to us very natural, since we are acquainted with an organ in them whose natural function would be to perform that office. The generative organs are, indeed, in perfect (female) individuals divided, as it were, into two parts of very distinct natures; the ovarium for the preparation of the germ and the production of the egg, and the oviduct and uterus, in which the ova are, as it were, incubated, and the germ and embryo sufficiently developed to allow of its being born. Now, it is actually the case that no true ovary has been discovered in the 'nursing' generations; on the contrary, the germs, as soon as they are perceptible, are situated in organs which must be regarded as oviducts and uteri, as, for instance, in the most perfect 'nurses' we are acquainted with, the *Aphides*. In the 'nurses' of the trematode larva, the *Cercaria echinata*, I have remarked that the germs in their earliest condition are collected into an organ at the root of the tail, which may probably be regarded as a uterus, and that they appear to distend this organ gradually to the size of the whole body. The accurate anatomical researches of Professor Eschricht on the *Salpæ* also show in the most precise way that the associated brood of the *Salpæ* does not originate from ova, but that, as germs which are arranged in a definite manner between the walls of a hollow organ, it is contained in what can in no case be an ovary, and which the author has termed a 'germ-tube.' This organ lies in a cavity which may probably be considered very nearly a uterus, which is however always, as it were, a secondary receptacle for the germs; but in the present instance it cannot be shown that they have occupied any previous receptacle or place of formation.

"From what we at present know, we may probably assume with some degree of certainty that the 'nursing' individuals are never themselves gemmiparous, but that they are born with germs in the organs in which the embryos are afterwards nourished; and from all this it appears as if the female generative organism were always divided in those cases in which development by means of 'nurses' occurs, so that as in the more perfect females an ovary especially is formed, so in the 'nursing' individuals a much-developed uterus is presented, in consequence of which, they, as individualised uteri, have assigned to them, as the object of their existence, the performance of the functions of a uterus, and their complete formation must thus necessarily precede that of the germs which are committed to their fostering care. We cannot readily perceive the reason, that because all 'nursing' individuals must be of the female sex, it should follow that all those individuals which feed the young should also be of that sex, and yet this seems to be the law. Anatomy shows us that the 'feeders' among bees, wasps, &c., and probably those of all insects living in regular societies, are females, whose sexual organs remain in an undeveloped state. They present scarcely the vestige of an ovary; the uterus is rudimentary, and all propagation consequently in the material way, so to say, is rendered impossible; the imperfection of the organ does not even allow of their acting as 'nurses,' and the propagative instinct in a physical, corporeal sense passes into a will for the propagation of the species, into a *nisus* impelling to the feeding or nourishing of the young; and the fulfilment of these impulsive duties is favoured by the peculiar transformation which some of the organs undergo at the expense of those intended for propagation, in order that they may become adapted to the bringing up of the young. Whence it follows that the development of the species in this case does not take place by means of several generations, but through several broods of the same generation. The reason of the great number of 'feeders,' and for the common good of 'workers,' so that they often constitute thousands, whilst the fertile individuals scarcely amount to hundreds, may be readily understood when we consider more closely the regular societies of bees and ants, and witness the labour required for the nourishment of the young. But, on the other hand, how the development of the species is promoted by the multitude of 'nursing' animals of which we often see thousands for each single fertile one, appears to us difficult of explantion, since, even all of them can only be regarded as animated organs, which do not appear to act for or with each other. It does not however seem to me improbable that even the *Aphides*, trematode nurses, and other parasites, which are so immediately injurious to the organisms in or upon which they live, are not destined merely to promote the extension of the species, but that they also induce in the organisms themselves conditions necessarily more and more favourable to a later generation; plants also and animals afford us many instances that to a certain abundance of parasites there usually succeeds a complete overflow of them.

"I conclude with the remark that, inasmuch as in the system of 'nursing' the whole advancement of the welfare of the young is effected only by a still and peaceful organic activity, is only a function of the vegetative life of the individual, so also all those forms of animals in whose development the 'nursing' system obtains, actually remind us of the propagation and vital cycle of plants. For it is peculiar to plants, and, as it were, their special characteristic, that the germ, the primordial individual in the vegetation or seed, is competent to produce individuals which are again capable of producing seeds or individuals of the primary form or that to which the plant owed its origin, only by the intervention of a whole series of generations. It is certainly the great triumph of Morphology, that it is able to show how the plant or tree (that colony of individuals arranged in accordance with a simple vegetative principle or fundamental law) unfolds itself, through a frequently long succession of generations, into individuals, becoming constantly more and more perfect, until, after the immediately precedent generation, it appears as calyx and corolla, with perfect male aud female individuals, stamens, and pistils (so that even in the vegetable kingdom the grosser hermaphroditism does not obtain, which is still supposed to take place in the animal); and after, the fructification brings forth seed, which again goes through the same course. It is this great and significant resemblance to the vegetable kingdom, which in my opinion is presented by the *Entozoa* and all 'nurse' generations, and to which I have alluded in the preceding Essay: I might almost say that the condition of continued depeudence incidental to the animal life, is to a certain extent one of less perfection than that which is presented in the progressive elevation in development effected by the agency of the vegetative life."

GENET. [VIVERRIDÆ.]

GENISTA (the Latin *Genista*), a genus of Plants belonging to the natural order *Leguminosæ*. The calyx is 2-lipped; the upper lip bifid, the lower trifid. It has a subulate ascending style; a terminal oblique introrse stigma. The species have yellow flowers, and most of them yield a yellow dye. The *Planta Genista*, or Whin, the Gen of the Celts, and the Gênet of the French, was the badge of a long race of English kings, hence called Plantagenets. Upwards of eighty species are included in this genus, but few are applied to any important uses. They are found principally in the south of Europe, and some few are natives of Great Britain.

G. pilosa, has a smooth procumbent stem, and obovate lanceolate obtuse leaves; ovate hlunt stipules. The peduncles, calyx, and underside of the leaf are silky, and the pods hairy. It is a uative of the south of France, and is also found in Suffolk and Cornwall in England, in sandy places.

G. tinctoria, Dyer's-Weed, or Woad, has a depressed stem, with erect branches, without thorns; lanceolate leaves, hairy at the edges; minute subulate stipules; racemose flowers; and glahrous corolla and pods. The branches are from one to two feet high, glabrous and downy above. This plant is a native of Europe, and is found in pastures, fields, and thickets in England. The flowers yield a yellow colour, which is much used for dying wool. When cows are allowed to feed on this plant their milk becomes bitter and disagreeable, and the unpleasant taste of cheese and butter is often attributable to this cause. *G. tinctoria* has also a medicinal reputation. The seeds act as a mild purgative, and the ashes are also said to be a valuable diurectic.

G. anglica, Needle-Whin, has a spinous ascending stem, leafless below; uuarmed glabrous flowing branches; ovate-lanceolate leaves; and glabrous stems and corolla. It is a native of Europe, in France and Denmark, and is found in Britain ou moist boggy commons.

G. acanthoclada has trifoliate leaves, nearly sessile; linear, complicated, silky leaflets; stiff and spinose branches. The flowers almost opposite, and disposed along the branches in a kind of interrupted spike. It is a native of the Levant in exposed places, and in the island of Melos. This plant appears to be the *Μέλαινα ῥίζα* of Hippocrates, *Σκορπίος* of Theophrastus, and the *Ἀσπάλαθος* of Dioscorides.

G. Hispanica has lanceolate villous leaves; branched stiff spines; terminal racemes, somewhat capitate. It is a native of Spain and the south of France. Fraas states that this species is the 'genista' of Roman writers (Virgil, 'Georg.' ii. 434; Pliny. xxvi. 9. 12, 22. 24, 9; Columella, 4, 31).

G. purgans is an erect branched shrub with very few leaves, and axillary flowers on short pedicels. It is a native of Frauce, on hills, especially in the Cevennes, where it is used hy the villagers as a cathartic.

G. monosperma has erect branches; very few linear oblong leaves, clothed with a depressed pubescence; and lateral few-flowered racemes. It is a uative of Spain, Portugal, Barbary, and Egypt. On the shores of Spain it is found to be very useful in binding the otherwise drifting sand, and by its beautiful fragrant blossoms it converts a barreu waste into a lovely garden. The goats feed on the leaves and young brauches, of which they are particularly fond. The Spaniards call both the plant and the districts over which they grow Retamas, from the Arabic word Rætam. The species of this genus thrive well in a mixture of loam, peat, and sand, and young cuttings will easily strike in a potful of sand with a bell glass over them, which must be taken off aud wiped occasioually, lest the cuttings absorb too much moisture.

(Don, *Dichlamydeous Plants*; Bahiugton, *Manual of British Botany*; Fraas, *Synopsis Plantarum Floræ Classicæ*; Burnett, *Outlines of Botany*.)

GENTIANA, a genus of Plants belonging to the natural order *Gentianaceæ*. It has a 4-5-parted calyx. The corolla is variously divided, twisted to the right in æstivation, often with accessory lobes between the principal ones, without depressed glands upon the petals. The filaments equal at the base; anthers not changiug. The stigmas are terminal on the ovary or style. The placentæ united with the endocarp and overspreading the valves of the capsule.

G. Catesbæi is found in wet grassy meadows in the southern parts of the North American Union. It has a branching fleshy root. The stem is simple, erect, and rough. The leaves opposite, ovate, or lanceolate, slightly 3-nerved, acute, rough on the margin. The flowers crowded, nearly sessile, axillary, and terminal. The segments of the calyx linear lanceolate, varying in length, exceeding the tube and sometimes more than twice its length. The corolla is large, blue, ventricose, plaited, its border 10-cleft; the 5 outer segments roundish and more or less acute, the 5 inuer hifid and fimbriate. The stameus are 5 in number, with dilated filaments, and sagittate anthers. The ovary is oblong, lanceolate, compressed, supported by a sort of pedicel. The style is absent, stigmas 2, oblong and reflexed. The capsule oblong, acuminate, 1-celled, and 2-valved. The dried root is mucilaginous and sweetish, then inteusely bitter, approaching to *G. lutea*. It is said to be the hest substitute for that species.

G. Amarella has a salver-shaped 4-5-cleft corolla, bearded in the throat; the calyx-lobes 5, nearly equal, lanceolate; the leaves sessile, ovate, lanceolate; the radical leaves obovate. It is very variable in size and in the number of the flowers. It is from 3 to 12 inches high, erect. The stem square, much branched. The flower is of a pale purple colour, barely an inch long; the mouth of the tube is crowned by a fine erect purplish fringe rather shorter than the limb, and rising much above the stameus. The stamens answer in number to the divisions of the calyx and corolla, being almost always 5, awl-shaped, with roundish separate anthers. The styles are very short; the stigmas ovate. This species is a British plaut, and is one of the suhstitutes for the true Gentian sold in shops.

G. campestris is rather paler than the last species and of more humble growth, varying greatly in luxuriauce. The stem is somewhat corymbose, with simple flower-stalks of various lengths. The leaves are ovate, acute, and 3-ribbed. The flowers are somewhat larger than in *G. Amarella*, 4-cleft, essentially distinguished hy having the two outer and opposite segments of the calyx ovate and very hroad, covering the two inner, which are narrow and lanceolate, or even awl-shaped, all deeply serrated, and minutely fringed. This species is found in Great Britain and in elevated pastures in many parts of Europe. It is used as a substitute for the officinal Gentian.

G. purpurea is native of Swizerland, Savoy, the Pyrenees, and Norway. It has a simple and sub-divided root, many-crowned, taper, thickish, long, yellow outside, white inside, inteusely bitter. The stem is obscurely 4-cornered, green or greenish-purple, from 1 to 2 feet high. The radical leaves are ovate, or ovate-lanceolate, apiculate; those iu the middle of the stem ovate-lanceolate, scarcely acuminate, the uppermost sessile, broad, lanceolate, uniting and sheathing at the base, all 5-nerved, flexible, aud bright shining green. The flowers are terminal and axillary on short stalks. The calyx is oblong, scarious, semi-transparent, slit longitudinally on the inner side. The corolla is large, rather coriaceous, with a few scattered dots arranged in rows iu the inside; the tube yellow and striated, the limb 6-cleft, with broad obtuse segments distant at the base. The seeds are brown, orbicular, and winged. It is employed with the next species in continental practice.

G. Pannonica has a tapering root, little branched, many-crowned, rugose, as much as 2 feet loug, thick, yellowish-brown outside, whitish inside. The stem is round, green, or purplish, from 1 to 2 feet high. The leaves are ovate, somewhat apiculate, 5-uerved, the petioles running dowu into a sheath, those on the middle of the stem ovate-lanceolate, long; those at the top acuminate, about 3-uerved; all somewhat coriaceous and bright green. The flowers are sessile, or on very short stalks (the upper whorl many-flowered), large, an iuch aud a half loug. The calyx is campauulate, obsoletely 5-cornered, about 6-cleft, varied with red and green; the segments almost leafy and unequal, divided by a wide sinus, sometimes serrulated, shorter than the tube. The corolla is coriaceous, membranous, purple, with a yellowish tube, marked all over into rows of deeper spots, the segments ovate, rather blunt, thrice as short as the tube. The seeds are brown, winged, and round. The roots are extremely bitter, and are used extensively in Bavaria and Austria in medicine.

G. Kurroo is found in various parts of the Himalayas. It has a stem about 1-flowered, obtuse leaves, the radical long, lanceolate, those on the stems linear. The teeth of the calyx are long and subulate. The corolla is funnel-shaped, with an intense blue spreading 10-lobed limb, the principal lobes of which are ovate and acute, the intermediate ones scale-like teeth. The root is used like Gentian in the north of Italy.

G. lutea, the Common Gentian, is found in alpine meadows throughout the middle of Europe. It has a cylindrical root, wrinkled, ringed, thick, forked, brown externally, yellow within. The stem is 3 or 4 feet high, hollow, and stout. The radical leaves are ovate-oblong, 5-nerved, 2 or 3 inches broad, those on the stem sessile, ovate, acute; those next the flowers cordate, amplexicaul, concave, all a pale bright green. The flowers are bright yellow, in many-flowered whorls, stalked. The calyx is of a papery texture, and semi-transparent, 3- or 4-cleft, with short lanceolate unequal segments. The corolla with a very short tube, and 5 or 6 green glands at the base, 5- or 6-parted, with oblong acute veiny lobes. The anthers are subulate, somewhat united, becoming distinct. The stigmas revolute. The capsule oblong and stalked. The seeds roundish, compressed, with a membranous brownish border. The root of this species furnishes the Gentian of commerce, a valuable bitter drug employed extensively in certain forms of dyspepsia, in intermittents, and as an anthelmintic. In full doses it is apt to relax the bowels, and it does not always agree with the stomach, in fact, it possesses a volatile principle capable of producing nausea and a kind of intoxication. The root contains a good deal of sugar and mucilage which enables the Swiss to prepare from it a liqueur held in high esteem among the people.

G. nivalis, *G. verna*, and *G. Pneumonanthe* are all described as British species.

The following is an arrangement of the European species of this genus:—

A. Tube of the corolla short or greatly enlarged at the mouth. Throat naked; segments not fringed.
- I. Flowers in whorls or heads.
  - *a*. Corolla without accessory plaits.
    G. lutea; *G. Thomasii*; *G. biloba*; *G. Charpentieri*; *G. Gaudiniana*.
  - *b*. Corolla with accessory plaits.
    1. Calyx a sheath deeply divided on one side.
       G. Burseii; *G. purpurea*; *G. macrophylla*.
    2. Calyx campanulate, with nearly equal teeth.
       G. Pannonica; *G. punctata*; *G. cruciata*.
- II. Flowers solitary or in pairs. Corolla with accessory plates.
  G. asclepiadea; *G. Pneumonanthe*; *G. Frœlichii*; *G. frigida*; *G. acaulis*; *G. excisa*.

B. Tube of the corolla cylindrical, or somewhat barreled. Throat naked. Segments not fringed.
- I. Perennial. Stems numerous, simple, 1-flowered.
  G. Bavarica; *G. brachyphylla*; *G. verna*; *G. æstiva*; *G. imbricata*; *G. pumila*; *G. Pyrenaica*.
- II. Annual. Stem single, branched, many-flowered. No barren shoots. Styles cloven.
  G. prostrata; *G. utriculosa*; *G. nivalis*.

C. Throat or corolla bearded. Root-leaves obovate; stalked.
- I. Calyx tubular, 4- or 5-toothed.
  G. campestris; *G. Germanica*; *G. Amarella*; *G. obtusifolia*;
- II. Calyx 4- or 5-partite. Stem branched only at the base. Flower-stalks long and naked.
  G. tenella; *G. nana*.

D. Throat naked. Segments of corolla fringed.
  G. ciliata.

As ornamental objects these plants are remarkable for the brilliant colours and beautiful forms of their flowers. The species are extremely numerous, inhabiting the temperate parts of Europe, Asia, and America, chiefly in mountainous situations, where they breathe a pure and rarified air, are exposed to bright light during the short summers of such regions, and although fixed during winter in places intensely cold, yet are so well prepared to resist it by the warmth of their summer, and so much protected by the snow that covers them, as to suffer no injury. These alpine plants are consequently difficult to cultivate, or even uncultivable, from the impossibility of imitating their natural atmosphere; and hence it is only a very small number that are ever seen in gardens. The prevailing colours of their flowers are either an intense pure blue, or a bright clear yellow: some idea may be formed of the brilliancy of the former from that of *G. acaulis*, a common species in gardens, where it is much employed for making edging to borders; the yellow species are equally represented by *G. lutea*.

The ornamental species that are found easily capable of cultivation are *G. lutea*, with yellow, and *G. asclepiadea*, *G. saponaria*, *G. cruciata*, *G. septemfida*, *G. acaulis*, and *G. Pneumonanthe*, with blue flowers. Of these all require a good American border of peat-earth to grow in, with the exception of *G. acaulis*, which prefers the hardest and stiffest clay. Many other species are named in gardening books, but they generally perish as soon as they are brought under the hands of the cultivator.

(Lindley, *Vegetable Kingdom*; Wood, *Tourists Flora*; Babington, *Manual of British Botany*.)

GENTIANA'CEÆ, *Gentianworts*, an extensive order of Plants belonging to the Monopetalous Exogens, and consisting of herbaceous plants, with opposite ribbed leaves, and flowers whose corolla is imbricated; the stamens alternate with the petals; the ovary superior, with two cells standing right and left of the axis of growth; and seeds containing a minute embryo lying in a mass of albumen. They are generally considered to be in the closest alliance with *Scrophulariaceæ*, but it is possible that their resemblance to that order is one of analogy rather than affinity. Along with *Orobanchaceæ* and *Monotropaceæ*, they seem rather to belong to the albuminous group of Exogens, as has already been shown. [EXOGENS.] The flowers of these plants are usually coloured with pure bright yellow, red, or blue, and in many cases they are on this account among the most beautiful of flowers; but if we have a high development of form and colour in the majority of the species of this order, so we also have in the Guayana and Mexican plants belonging to the genus *Voyra* or *Leiphaimos* the brown leafless habit and low development of *Orobanche*. This order is famous for its bitterness, which seems to pervade all the species. *Gentiana* itself furnishes all the officinal kinds; but *Erythræa Centaurium* [ERYTHRÆA], a beautiful wild flower common in many parts of England, is advantageously employed by country people as a substitute; and the root of *Frazera Walteri* [FRAZERA] has been used as a means of adulterating the bitter Calumba-root. *Cherayta*, a Himalayan annual, is remarkable for the pureness of its bitter. The whole plant is pulled up at the time the flowers begin to decay, and dried for use. There are 60 genera and 450 species of this order.

2 3 1

Common Gentian (*Gentiana lutea*).

1, a capsule; the same cut across to show the placentæ; 3, a vertical section of a magnified seed.

This order extends over almost all parts of the world, from the regions of perpetual snow upon the summits of the mountains of Europe, to the hottest sands of South America and India. They however do not appear in the Flora of Melville Island; and they form part of that of the Straits of Magellan. The most common genus is *Gentiana*, than which few genera display so full a series of colours in the flowers; red, blue, yellow, and white are all exhibited in it, with many of the intermediate compound tints. For the properties of the genera of this order see CICENDIA, CHLORA, MENYANTHES, VILLARSIA, AGATHOTES.

GENUS, an assemblage of species allied by common characters, and subordinate to an order, family, tribe, or sub-tribe. A genus is frequently a natural assemblage, but almost every naturalist has his own particular views with regard to the propriety of uniting or separating particular groups of species; it is therefore often an arbitrary group. It is thus that the synonymy of genera becomes every day more copious, and it is one of the difficulties with which the naturalist has to contend in his studies. At present there are no generally recognised rules for the construction of genera amongst plants and animals. [FAMILIES OF PLANTS; ORDERS; SPECIES.]

GEOBDELLA. [ANNELIDA.]

GEOCICHLA, a genus of Birds established by Mr. Gould for a pretty species resembling the Redbreast (*Erithacus Rubecula*, Swainson). It belongs, he observes, to an interesting group which was first characterised by M. Kuhl, and of which the collection of the Zoological Society possesses four well-marked species. ('Zoological Proceedings,' 1836.)

GEOCOCHLIDES, Latreille's name for the Shell-Snails. Trachélipodes Colimacéa of Lamarck; Limacinés of De Blainville; Limaçons of De Férussac.

GEOCRONITE, a Mineral occurring amorphous without cleavage. The fracture is lamellar in one direction, and in the other granular and conchoidal. The colour lead-gray; streak the same. Hardness between mica and calcareous spar. Lustre metallic. Opaque. Specific gravity 5·88. It is found in the silver-mine of Scala in Sweden, and in the province of Galicia in Spain. An analysis of the mineral from the Scala mine by Svanberg gives—

Lead	66·452
Antimony	9·516
Arsenic	4·695
Copper	1·514
Iron	0·417
Zinc	0·111
Sulphur	16·262

GEMOEYDÆ. [CHELONIA.]

GEOFFRÆA, a genus of Plants belonging to the natural order *Leguminosæ*. One of the species, *G. inermis*, sometimes known as *Andira inermis*, is a native of Jamaica, Trinidad, Martinico, Porto Rico, St. Domingo, and Guyana, in woods and on river-banks. It has 13 or 15 ovate-lanceolate leaflets, acute, glabrous on both surfaces, the flowers pannicled on short pedicles; calyx urceolate, clothed with rusty pubescence. The flowers are arranged in terminal and axillary ferruginous panicles, very showy, with reddish lilac petals. The legume is the size of a large plum.

The bark of this tree is of a grey colour externally, but black and furrowed on the inside. The powder looks like jalap. It has a mucilaginous and sweetish taste, and a disagreeable smell. Its medical effects are great. When properly exhibited it operates as a powerful anthelmintic. It is given in the form of a powder, decoction, syrup, and extract, but should always be given in small doses; in large doses it is poisonous, producing violent vomiting, with fever and delirium.

GEOLOGY, the science of the earth (as the Greek words γῆ and λόγος may be translated), includes, in a large sense, all acquired or possible knowledge of the natural phenomena on and within the globe; whether these be now of frequent occurrence, the result of the existing combinations of physical agencies, or remain as monuments and measures of those agencies in earlier periods of the history of the planet.

Some of these phenomena are witnessed in connection with inorganic bodies, and depend in a great degree on the laws of force which appertain to and distinguish from each other the particles of matter; others are exemplified in organised structures endowed with vital functions related to those structures; and there may yet be distinguished a third order of effects, influencing and combining with both of the former, and depending on laws of force which affect the whole mass of the globe, as gravitation, or derived from extraneous agency, as light.

If at any certain epoch (as the present time) the phenomena thus classed were known in detail, and reduced to general laws which truly expressed the individual cases, the actual condition of the earth would be really known; if further it were possible to collect sufficient evidence from monuments preserved in the earth of its exact state at some former epoch, the variations to which terrestrial phenomena are subject would be disclosed; and by the comparison of several such surveys, taken at distant times, the laws of these variations would be revealed with an exactness proportioned to the certainty with which the intervals of time were determined. These laws of the variation of the condition of the globe at successive epochs, combined with the laws of chemical, vital, and mechanical action, which are assumed to be essential and constant, independent of time, and exempt from change, will furnish one, and only one, satisfactory general contemplation or theory of the origin, structure, and successive changes of the globe, considered as part of the planetary system revolving round the sun.

To reach this general theory is the ultimate object of modern geology. The discovery of the right method of proceeding in this attempt is of modern date; and all the most important steps of the advance towards this 'high point of knowledge' have been taken within the memory of the generation now passing away. If, as Sir John Herschel tells us ('Discourse on the Study of Natural Philosophy'), "geology, in the magnitude and sublimity of the objects of which it treats, undoubtedly ranks, in the scale of the sciences, next to astronomy," it owes this distinction to the fact that its modern cultivators have sought within the ranks of inductive science better methods of research and purer models of reasoning than those afforded by the treasures of ancient philosophy which have been preserved to our time. Nor is this the peculiar boast of geology. Every branch of the study of nature was equally transformed by the introduction of the Baconian methods of interpretation of nature; all the natural sciences have advanced together; the knowledge of the constant laws in the visible creation has been continually perfected; and thus, while the study of the long-past operations of nature has been imbued with the exactness of chemical, zoological, botanical, and physical research, the dry annals of one era in the history of the world have been enriched into a long, instructive, and eventful history.

Among the ancients the notices of geology are few, and the interest belonging to them is of a peculiar character. When chemistry, whose operations manifest the existence of peculiar laws of force among the particles of matter, was wholly unknown—when the living wonders of creation were but slightly considered by philosophers intent on abstract principles—no accurate survey could be taken of the condition of any one part of the surface of the earth. But a small part of that surface was known to any one people, and only in a few situations were the changes in the aspect of nature so extensive as to arrest the attention of the geographer, or so violent as to excite the philosopher to search for the cause.

Among the anciently peopled and commercial states of the eastern shores and islands of the Mediterranean both these circumstances concurred, and there first awakened the powerful intellect of Greece to speculation on the varying condition of the land and sea. Lower Egypt is the gift of the Nile, and the learned people which possessed it were compelled by the circumstances of their situation to study the nature and effects of the annual floods of the river. Herodotus (born B.C. 484) estimates (ii. 11) that the Nile, if diverted into the Red Sea, would fill that long gulf in less than 20,000 or even 10,000 years. The notion of change thus distinctly impressed upon the minds of the Egyptian priests was developed in a general and philosophical form, and illustrated by special references to an extended series of geological phenomena by their pupil Pythagoras (born B.C. 586). According to the summary of their doctrine, and the tenor of the illustrations of it which are given by Ovid, we cannot avoid seeing, even through the injurious ornament of verse, that Pythagoras had acquired a clear conception, a 'distinct idea,' of nature as existing by the concurrent action of many complicated powers, which were subject to continual or sudden variation in their relative intensity. Changes of the relative level of land and sea, and divulsion of islands from the mainland by the action of earthquakes, are distinctly announced; the displacement and limited duration of volcanic vents, such as Ætna; the degradation of land by the action of atmospheric agency ('et eluvie mons est deductus in æquor;') the submersion of land which had been formerly peopled—

> Si quæras Helicen et Burin, Achaidas urbes,
> Invenies sub aquis.—(Ovid, 'Metam.' xv., l. 293.)

the production of new land, and the occurrence of marine shells far from the present seas;—these phænomena, distinctly observed and analysed, and clearly produced in proof of a general proposition, justify a higher degree of admiration for the Samian philosopher than is due to any of the merely speculative writers of antiquity.

Similar observations appear to have served as the ground-work of Aristotle's exposition ('Meteorologica') of the perpetual fluctuation of natural phenomena; the alternate excitation and rest of parts of the earth's surface. But it is in Strabo that we find the most sensible views of the causes of the occurrence of marine shells far from the shore, the displacements of land and sea, the rising of islands, the formation of straits, and other great geological phenomena.

Having stated the views of Eratosthenes, as to the general fact of the earth's globular form, and the production of the numerous minor inequalities on its surface, by correspondingly numerous 'proximate causes,' such as the operations of water, heat, concussions, vapours, and the like, he examines the opinions of Xanthus and Straton, which Eratosthenes had preserved. (Strabo, Casaub. 49, &c.)

The explanation of Xanthus (derived from an historical fact) that the phenomena in question were due to great droughts which had diminished the originally greater expanse of the sea, is regarded as insufficient; and Strabo's hypothesis of adjacent but disconnected seas, one of which being raised to a higher level by sediment on its bed, had forcibly opened itself a passage to the other, the Euxine to the Propontis, the Mediterranean to the Atlantic, is shown to contradict received physical theorems. Strabo proposes to account for these and other phenomena by the general speculation that the land, not the sea, is subject to changes of level, and that such changes more easily happen to the land below the sea, 'because of its humidity.'

The action of Ætna in moving the shores of Sicily and Italy is spoken of in a familiar manner, and a long description of phenomena bearing on the discussions succeeds, in which the opinions of many authors are quoted.

Fifteen hundred years elapsed after the era of Strabo, without adding anything material to the stock of geological facts, or the limited range of rational theory; for, excepting the work of Omar (10th century), in which the phenomena of 'new lands,' and marine shells found inland, are referred to a 'retreat of the sea,' there is not, on the subject of geology among the Arabian writers, even the usual amount of comment on the writers of Greece and Rome which characterises the literary efforts of the learned Moslems. (Lyell, 'Principles of Geology.')

In modern times Italy, the fruitful mother of modern physical science, offered in her volcanic cones, ranges of mountains, and shelly marls at their bases, the most attractive points to the intellectual activity of the precursors and contemporaries of Galileo.

So recent are sound views of the true nature and relations of the organic forms buried in the earth, that it is not very difficult for English geologists to imagine the fierceness of the contest in which Fracastoro (1517) was involved, to defend his opinions that the 'formed stones' (as they were afterwards termed in England) were not 'lusus naturæ' produced by a 'plastic force,' but really the remains of fishes, mollusca, &c.; and that they had not been rudely scattered over the surface by the Noachian flood, but buried at great depths by a more regular operation of water. These important assertions were the subject of controversy for nearly two centuries in Italy; and in establishing the true nature of the organic remains, Cardano, Colonna (1666), and Scilla (1670) overlooked or disregarded the more serious and more seducing error of ascribing their inhumation in the earth to a general deluge. Georgius Agricola (1546) adopted the wrong view of the origin of organic fossils: but Steno (1669) of Copenhagen, opened a new line of inquiry, by noticing the succession of rocks; distinguishing some as having been formed before the creation of animals and plants; insisting on the original horizontal position of the strata; the proof of violent movement of the crust of the globe, afforded by the now inclined position of such strata in mountainous countries; and the variations of condition to which the surface of Tuscany had been exposed, by repeated overflows and retirements of the sea. (Lyell, 'Principles.')

Scilla's masterly work on the organic remains of Calabria, published both in Latin and Italian ('La Vana Speculazione disingannata dal Senso,' 1670), may be considered as closing the long dispute in Italy, among men of philosophical minds, on the subject of the nature of organic fossils. Its course was comparatively very short in England, for Plot (in 1677) is almost the only writer who really and heartily embraced the doctrine of an occult cause, to escape from the consequence of admitting the true origin of the 'formed stones,' and Scilla's work was abridged for the 'Philosophical Transactions' in 1695-6, by Dr. Wotton. Lister's early views on the matter (1678) express a doubt, arising from knowledge; he saw that the fossil-shells were different from the living types, and proposed the alternative of a terrigenous origin, or an extinction of species. Ray (1692) on 'Chaos and Creation,' Woodward's 'Natural History' (1695), Scheuchzer's 'Herbarium Diluvianum,' of the same date, afford proof of the victory gained by the observations of naturalists over the closet speculations of metaphysicians, on the origin of fossil-shells in most parts of Europe; and indeed, in France, Palissy's lectures and writings (his last publication bears the date of 1580) may be said to have established the truth contended for.

The victory was unproductive. In consequence of coupling with the obvious truth a fatal and fundamental error, the shells and other exuviæ of the sea were maintained by Woodward and a host of contemporaries and followers to have been brought upon the land by the 'universal deluge,' as all writers except Quirini (1676) agreed to term the Noachian flood. This error might speedily have been swept away by the early arguments of Palissy, the investigations of Steno, and the striking generalisation of Lister; but that, unhappily, from a philosophical question, it became a theological argument. The fossil-shells far from the sea were held to be physical proofs of the truth of the Mosaic narrative; and the occurrence of these shells at various depths and heights, and in rocks of different kinds, only furnished additional arguments in favour of the violence of that flood, which not merely was supposed to have covered the mountains, but to have entirely broken up and dissolved the whole frame-work of the earth, and to have deposited the materials according to their relative gravity. In vain had Hooke, Ramazzini, and Ray, previous to 1700, protested against the absurdity of this hypothesis, which Leibnitz appears to have despised; it was reserved for Moro (1740), Buffon (1749), Linnæus (1770), and Whitehurst (1792), to hasten its banishment from philosophy; but even at this day there are persons who from time to time revive the discussions of the 16th century, as a point of importance in Christian theology.

To account for the dryness and elevation of the countries where fossil shells occur, there are but two hypotheses: the shelly bed of the sea has been raised, or the ocean has abandoned its ancient place. Many of the Italian geologists adopted the former view, and in consequence repeated the opinions and reasonings of Strabo, with the advantage of referring to the elevation of Monte Nuovo near Puzzuoli, in 1538, and Santorino, 1707 (Majoli, 1597; Vallisneri, 1721; Lazzaro Moro, 1740). The better order of English writers (Hooke in 1668, Ray in 1692—earthquakes were then frequent in Europe) adopted the same views; and Hooke in particular presented the phenomena of earthquakes and volcanoes in the form of a general speculation, which served to direct the opinions of subsequent systematists like Whitehurst.

None of the philosophers who were concerned in establishing the truths connected with organic remains were seduced by their success into the vanity of proposing any general hypothesis on the formation of the earth. But this creditable modesty, so characteristic of the spirit of induction which animated Fracastoro, was not at all imitated by the fanciful diluvialists, who followed in the wake of Woodward, Burnet, Whiston, Catcott, and others. To determine whence came the water which held at once in suspension the whole of the exterior parts of the globe, and whither it retreated, was necessary to help out their extravagant proposition.

No ordinary hypothesis would meet these formidable problems, and if we recollect that in answering them it was further required to adopt views which should not trench on the arbitrary notions then entertained as to the meaning of certain passages of Scripture, we shall be disposed to regard even the monstrous violations of physical truth which appear in the hypothesis of Burnet, Woodward, and Whiston, without surprise. Omitting minor circumstances which it would be useless to particularise, Burnet, Woodward, and their followers, agreed in adopting the notion of an interior abyss below the crust of the earth, as the general reservoir from whence the waters rushed to cover the earth, and into which they again withdrew after the diluvial devastation was completed. Whiston, who was far better versed in physical science than either of the others, introduced in addition the notion of extraneous force; he brought a comet to envelop the earth in its misty tail, to cause violent rains, raise vast tides in the internal abyss, and thus effectually destroy the external crust of the planet. It appears probable that mankind seldom permit their imaginations to take such dangerous flights without necessity; the hypothesis is made to suit the conditions of the moment, and the chief error consisted in including among these conditions a narrow and unreasonable interpretation of the Mosaic narrative.

The diluvial hypothesis has been sufficiently traced to its natural consequence—a monstrous violation of the laws of nature; another general view, first distinctly stated by Vallisneri (1721), has been the source of long-continued errors. Struck by the general diffusion of marine fossils, he supposed the ocean to have once extended over all the earth, and to have gradually subsided, leaving everywhere the traces, not of a violent flood, but of the quiet super-fluctuation of water. Perhaps Vallisneri found this notion in his travels; at any rate, the notion of a universal subsidence of the ocean appears to be the German element of geological hypothesis, for Werner made it the basis of his so-called theory of the earth, and thus obscured with a physical improbability the important truths which he had established concerning the succession of strata.

Starting from an entirely different point, Leibnitz (in 1680) proposed one of the most general contemplations which has ever appeared in geology. He commences with the concentration of the mass of the globe in a state of great heat; accounts for the fundamental primary rocks by the refrigeration of the surface, and explains the violent action of water upon them by the collapse of this crust on the contracting nucleus. Sedimentary strata are the natural consequence of these watery movements subsiding to rest, and by the repetition of the phenomena such features are imparted to the earth as to insulate many of the later deposits, and render it necessary to be prudent in determining whether local or general agency has been concerned in producing them. It would be difficult in general terms more clearly to announce views now prevalent among those who contemplate geology in connection with physical science. Cordier, Von Buch, and De Beaumont have endeavoured by this speculation of Leibnitz to explain some of the principal phenomena of geology—the elevation of mountains; but the merit of Leibnitz's theoretical views was little regarded in England till Mr. Conybeare explained his views to the British Association at Oxford at its first meeting in that city in 1833.

The effect of Laplace's and Fourier's theorems on the operation of interior heat have been augmented by Mr. Hopkins's labours; and the grand views of Sir W. Herschel as to the constitution of the universe have been applied to the history of the earth by Sir Henry De la Beche.

In the works of Ray (1692), and Hooke (1688), we may trace the revival of another general speculation (that of Pythagoras), which, instead of deducing the leading geological appearances from some primal condition, with Leibnitz, supposes the essential condition of the world to be one of continual change, and assigns to modern causes in action a measure of force capable of producing, in a sufficient lapse of time, phenomena as important as those of ancient geological date.

Lazzaro Moro's views (1740) have the same tendency to recall speculation to the enployment of real causes seen in daily operation; Buffon (1749) appears to have unsuccessfully attempted the union of the fundamental view of Leibnitz and the regard for existing agencies shown by Ray; Dr. James Hutton, of Edinburgh, rejected all inquiry as to the beginning of the world, and gave himself up entirely to an explanation of the phenomena visible in the crust of the earth, on the principle of a continual degradation of land by atmospheric agency, the consequent formation of sedimentary strata on the bed of the sea, and the periodical compensation of these effects by the action of internal heat raising the bed of the sea, with the stratified deposits thereon. A continual destruction of the existing land through the agency of water, and an occasional uplifting of new continents from the ocean bed—these are the most striking points of the Huttonian theory of the earth. Sir Charles Lyell differs from Dr. Hutton chiefly by recurring to the original form of the speculation as we may conceive it to have existed in the mind of Pythagoras or Aristotle, could either of those men have become acquainted with modern science. For, instead of the occasional occurrence of a violent upward movement of the bed of the sea, the author of the 'Principles of Geology,' contends for a continual compensation among the agencies of nature, the perfect equality of modern and ancient physical forces, and the possibility of explaining all, even the grandest, of ancient geological phenomena by causes now acting, and acting with their present intensity. No more definite or general proposition has ever been advanced in geology, and its effects have been everywhere evident in the advancement of geological science.

Geological appearances are usually of a complicated character, and must be analysed into their elementary parts before the inductive process, which requires the comparison of facts agreeing or differing with respect to a certain quality, can be usefully applied. Fossil shells must be distinguished into fluviatile or marine, identical with or different from recent kinds; rocks must be considered as to their chemical nature, mechanical structure, geographical and other characters, before any valuable inferences can be gathered from them. Though this kind of labour is not discoverable among the works of the Greeks which remain to us, we must not hastily deny that they attempted it. In modern times Fracastoro, Palissy, and Steno, by distinguishing the groups of strata; Lister, by discriminating recent and fossil species of shells, and by noticing the geographical relations of rocks; Woodward, by his industrious collection of specimens and methods of arrangement; Packe, by his remarkable chorographical map of Kent; Lehman (1756) and Arduino, by their classification of rocks, according to the relative periods of their production; and Mitchell (1760), by his masterly determinations concerning the relation between the ranges of mountains and the inclinations of the neighbouring strata—have stronger claims to grateful remembrance than are due to those who with much labour have merely produced volumes of empty speculation.

John Gottlob Lehman (1756) may be considered as having the best claim to a clear enunciation and proof of the different age and relative position of classes of stratified rocks. In the French translation of his work ('Traité du Physique, d'Histoire Naturelle, de Mineralogie, et de Metallurgie') he says, "Nothing is more natural than to group all mountains in three classes. The first includes mountains which are coeval with the formation of the globe; the second class was produced by a revolution co-extensive with its surface; the third consists of mountains which owe their origin to particular accidents or local revolutions." This was not a mere speculation of what might be convenient, for he adds, "The mountains of the first class are high, sometimes insulated in the plains, but generally connected in a chain, traversing considerable parts of the earth. They differ from those of the second class by their elevation and extent, by their interior structure, by the mineral substances associated with them."

Pallas ('Journal de Physique,' 1779), in addition to these general views, maintains that the granitic rocks, then taken as primary, were never formed by water, because they do not occur in beds, nor contain organic remains; that the secondary mountains were produced from the disintegration of granite; and the strata of later date, by the wrecks of the sea elevated and transported by volcanic eruptions and subsequent inundations.

To these distinguished authors Werner, professor of mineralogy in Freyberg (1775), was a worthy successor. The first important addition made by him to our previous knowledge on the subject was contained in his 'Kürze Klassifikation und Beschreibung der verschiedenen Gebirgsarten' (1787), where the mineralogical distinctions of rocks may be viewed as a completion of the labours of the earlier Swedish writers, Cronstadt, Wallerius, Linnæus, &c., all of whom had glimpses of the geological relations of the rocks they classified. It does not appear that Werner proposed any views as to the geological relations of rocks in advance of those of Lehman or Pallas till 1790 or 1791, when the doctrine of 'formations' was explained in his lectures, which indeed was a powerful mode of diffusing instruction; for his amiable manners, disinterested enthusiasm, and various knowledge gave him a strong ascendency over the numerous pupils who, from various countries, flocked to Freyberg. In 1795 Werner had matured his views as to the classification of all the stratified rocks, and from this it is easy to estimate the real claim of Werner to a high place in the ranks of modern geology. The great advance made by Werner consists not in propounding the distinctions of great classes of rocks, for this had become a common idea in Europe, but in practically analysing these classes into their constitutent groups, tracing the order of succession among them, assigning their mineralogical characters to each, and generalising this local truth into the doctrine of formations universally succeeding one another in a settled order of time. Parting from Freyberg with a better method of mineralogy, and a more developed system of the succession of rocks than was previously known, the pupils of Werner carried the influence of his name and opinions over the world, and, unfortunately, the crude hypothesis which was connected with the rich truths he taught was embraced with an ardour very disproportionate to its value.

In France Rouelle (about 1760) had acquired ideas apparently as general, and fully as well supported by local knowledge, as Lehman. His views on organic remains were quite in advance of the time. In England the notices of stratification by Mr. Strachey ('Phil. Trans.,' 1719), the Rev. B. Holloway (1723), and the Rev. John Mitchell (1760) are of great importance. Strachey presents an accurate section of the coal strata of Somersetshire, with reflections on the strata above them, and their geographical boundaries; Holloway describes the geographical relation of the sand-hills of Woburn and Shotover, yielding fullers'-earth, to the chalk hills on the east, and the oolitic tracts on the west; but Mitchell enters into a general and masterly discussion on the relation between geological structure and the geographical features of the surface not to be paralleled for fully fifty years.

Whitehurst must here be mentioned with honour. His 'Inquiry into the Original State and Formation of the Earth,' 1778, is of small value for the purpose he proposed, but it contains important facts towards a right conception of the structure of the earth. His 16th chapter, entitled 'The Strata of Derbyshire and other parts of England,' is full of information, principally derived from the miners, but evidently well methodised in his own mind. How could the geologists of England neglect such passages as these following, which are merely the scientific exposition of truths known for hundreds of years previous by skilful miners in all regions of stratified rocks?—"The arrangement of the strata in general is such that they invariably follow each other, as it were, in alphabetical order, or as a series of numbers, whatever may be their different denominations. Not that the strata are alike in all the different regions of the earth, either with respect to thickness or quality, for experience shows the contrary; but that the order of the strata in each particular part, how much soever they may differ as to quality, yet follow each other in a regular succession, both as to thickness and quality—insomuch that by knowing the incumbent stratum, together with the arrangement thereof in any particular part of the earth, we come to a perfect knowledge of all the inferior beds, so far as they have been previously discovered in the adjacent country." (Edit. of 1792, pp. 178, 179.) In p. 186 is the following remark in capitals:—"N.B. No vegetable forms have yet been discovered in any of the limestone strata."

From these notices it is very clear that a distinct perception of a fixed order in the succession of strata was so prevalent in the mining districts of England as to attract the attention of the well-informed classes of society. But it is extraordinary that Mitchell, who was appointed Woodwardian professor in 1792 (according to Farey), and by his physical and mathematical knowledge seemed especially able to work out the whole system of English stratification, should, on his retirement from Cambridge to his rectory of Thornhill in Yorkshire, have contented himself with tracing the succession of strata in the north of England, or rather between Cambridge and Thornhill, and communicating the document to Smeaton, without giving it even to the Royal Society, which had published his early papers. Had this been done, or had Smeaton known the value of the paper put into his hands, it could not have happened, that of all the able engineers who before 1790 were engaged in surveys and executing canals, not a man should have attended to information of such singular value in his profession; nor would Dr. William Smith have been occupied in re-discovering some of the truths which constitute the foundation of English geology.

The progress of Dr. Smith's discoveries in geology is easily traced. Commencing his career as a surveyor of land, and afterwards acquiring great employment as a civil engineer, his attention was drawn in 1787 to the obvious distinctions in the soils and the subjacent strata of certain parts of Oxfordshire and Warwickshire, which occupied, with regard to one another, a certain geographical relation. In 1790 and 1791 the same relative position of the same strata was forced on his attention in Somersetshire, with the addition of a series of coal strata below the oolite, lias, and red marls with which he was previously familiar. Assured by his own observation that the local knowledge of the mines of Somersetshire which Strachey had published in 1719 was only a part of the truth, he set himself not to frame a hypothesis, but to determine the extent of the regular succession of strata in the vicinity of Bath, drew accurate sections of the strata in the order of superposition, ascertained amongst them a general dip to the east, marked their ranges on a map of the surface, and in 1794, in the course of a professional journey from Bath into the north of England, examined impartially whether the general features of stratification in other parts of England corresponded with the impression fixed in his mind by abundant evidence, near Bath, that one general order of succession of the strata could be traced throughout the island, with a general dip to the east or south-east. The result confirmed his view, and excited him to devote time, professional income, and unequalled labour to produce proof satisfactory to others. The result was a geological map of England and Wales, drawn previous to 1801, when proposals were issued for the publication of it.

The strong conviction in his mind of the regular, orderly, and successive deposition of the strata, led him to a more minute analysis of the characteristic marks of the several deposits than had ever been conceived before. The remarkable resemblance and occasional proximity of many rocks near Bath, belonging to different places in the section of strata, and which (to use a favourite expression of Dr. Smith) "had been successively the bed of the sea," prevented any merely mineral distinction from being effectual; and he was thus forced to study with care the method of distribution of the fossil organic remains in the rocks for the purpose of discriminating these similar deposits. This was not long pursued before the local peculiarities of the strata in this respect were connected to a general law; and it was found that throughout the district in question the fossils were definitely located in the rocks; each stratum had its own peculiar species, wherever it occurred, and could thus be identified when in detached masses and in distant localities. This great discovery was recorded as a thing fully determined in a table of the Order of Strata in 1799, of which copies were distributed beyond the British Islands. The clear idea of each stratum being successively the bed of the sea is apparently the germ of that happy expansion of geological truths, unmixed with hypothesis and unfettered by a formula of merely local stratification, for which English geology is indebted to Dr. Smith. Such an idea immediately suggests, not a speculation in cosmogony, but various yet harmonious researches in the full spirit of inductive science. The history of successive geological periods, all characterisable by their chemical or mechanical products and contemporaneous organic existence, was thus placed in a concentrated light as a general problem for inquiry, and the effects were immediately obvious in the employment of organic remains, and sections and maps of strata, to determine the true condition of the land and sea from the earliest periods to the present hour.

Against the hypothesis of Woodward, that the fossil exuviæ in the rocks were lodged in them by the 'universal deluge,' it was objected, that though the fossil shells, corals, fish-teeth, &c., resembled the recent kinds, they were not the same. The question thus raised could not rest. Lister affirmed that in general the fossil species of shells were entirely distinct from living forms; Camerarius inquired to what marine genus of animals Woodward referred the belemnites, and received for reply that it was a mere mineral! The ammonites were admitted to be not nautili, but were declared to be 'Pelagian shells' not likely to be thrown on the present sea-coasts by the moderate force of tides and storms, which do not influence the deep parts of the ocean. Linnæus continually points out the species of corals and shells to which no recent analogue is known; and Solander, by giving suitable names to the extinct shells of Hordwell Cliff, figured by Brander (1766), opened the way to the researches of Martin, Parkinson, Sowerby, Brocchi, Deshayes, Goldfuss, and more modern writers.

Llwyd and Scheuchzer commenced the study of fossil plants, which has lately been so much advanced by Sternberg, Adolphe Brongniart, Lindley, and Joseph Hooker. But by none of those writers who compared the fossil and recent worlds of life under the aspects of zoology and botany only could any clear notion be formed of the existence and destruction of a succession of different races of animals and plants. Lister had noticed the constant occurrence of a certain belemnite in the red layers at the base of the chalk; Morton had distinguished the geological position of some fossils in Northamptonshire; and Llwyd and Woodward had some knowledge of this kind. Rouelle and Werner have claims to attention, but certainly it is to Dr. William Smith that we owe the introduction of the important doctrine, that during the formation of the stratified crust of the earth, the races of animals and plants were often and completely changed, so that each stratified rock became in his eyes the museum of that age of the world, containing a peculiar suite of organic exuviæ, the remains of the creatures then in existence.

In France the same truth was put in a bright light by the successful labours of Cuvier and Alex. Brongniart in the vicinity of Paris; the former of whom, by his great anatomical skill, succeeded in restoring the vanished forms of many quadrupeds, different from those which now live; while the latter, collecting materials with great judgment from a wide field of research, brought the most convincing proof of the almost total dissimilitude between the forms of life of the secondary and tertiary periods of geology, while both were for the most part distinct from those of the actual land and sea.

The general doctrine of many successive creations of life in the globe, thus firmly established in England and France, was speedily acknowledged in every country where accurate observations could be made, and it only remained to trace out its consequences, and apply them to particular problems. One very successful effort of this kind has been made by M. Deshayes and Sir Charles Lyell, who, observing among a vast number of the tertiary fossil shells which are different from existing types, some few of which are identical with them, proposed to determine what variation there might be in the proportion of yet existing species among the tertiary fossils from different localities and deposits of a different geological age. As a general result (subject to exceptions) it may be stated, that the more recent the strata the greater the amount of resemblance between their fossil contents and the existing creation—a result in harmony with general views of the whole subject of the analogy of recent and fossil forms. Hence arises a method of classification for these strata of peculiar interest and power, though its successful application may for a time be delayed, till the philosophy of organic remains be more perfectly developed.

Without maps and sections of particular districts, representing the extent, thickness, and order of superposition of the several component rocks, the abstract truths of geology could never become of general interest or public value. Until the whole of the land be thus surveyed and described geological inferences may be insecure; it is therefore gratifying to reflect, that since Dr. Smith first proposed to publish a geological map of England (1801), a considerable part of Europe has been thus delineated. The first idea of such a map was given by Lister in a communication to the Royal Society in 1683; Mitchell's descriptions in 1760 are such as to make it surprising that no map came from his hands. The Wernerian school of geognosy produced none, we believe, so early as those few maps of the Board of Agriculture in England (1794), which contained delineations of soils, and occasionally of the rocks which gave them their distinctive qualities. In this respect Dr. Smith had no precursor; and when his map of the strata of England and Wales was produced, in 1815, it had no rival. Since this time maps of England have been published by Greenough, Phillips, Murchison, Knipe, and others. The geological survey of Great Britain is also going on. Mr. Griffith has published a map of Ireland; Dr. M'Culloch a map of Scotland; Von Buch's great map of Germany is published; the Mining Engineers of France are completing their survey of that country; the United States of America have made great progress in a similar labour; and the number of topographical works illustrated by maps and sections is innumerable. Before many years have passed, the whole accessible surface of the land will have been mapped by geologists.

We may conclude this historical sketch of the progress of geology with the following remarks from Sir Charles Lyell's 'Principles of Geology:—

"A distinguished modern writer has with truth remarked, that the advancement of three of the main divisions of geological inquiry have during the last half century been promoted successively by three different nations of Europe — the Germans, the English, and the French. We have seen that the systematic study of what may be called Mineralogical Geology had its origin and chief point of activity in Germany, where Werner first described with precision the mineral characters of rocks. The classification of the secondary formations, each marked by their peculiar fossils, belongs in a great measure to England, where the labours, before alluded to, of Smith, and those of the most active members of the Geological Society of London, were steadily directed to these objects. The foundation of the third branch, that relating to the tertiary formations, was laid in France by the splendid work of Cuvier and Brongniart, published in 1808, 'On the Mineral Geography and Organic Remains of the Neighbourhood of Paris.' We may still trace in the language of the science, and our present methods of arrangement, the various countries where the growth of these several departments of geology was at different times promoted. Many names of simple minerals and rocks remain to this day German, while the European divisions of the secondary strata are in great part English, and are indeed often founded too exclusively on English types. Lastly, the subdivisions first established of the succession of strata in the Paris basin have served as normal groups to which other tertiary deposits throughout Europe have been compared, even in cases where this standard was wholly inapplicable. No period could have been more fortunate for the discovery, in the immediate neighbourhood of Paris, of a rich store of well-preserved fossils, than the commencement of the present century; for at no former era had Natural History been cultivated with such enthusiasm in the French metropolis. The labours of Cuvier in comparative osteology, and of Lamarck in recent and fossil shells, had raised these departments of study to a rank of which they had never previously been deemed susceptible. Their investigations had eventually a powerful effect in dispelling the illusion which had long prevailed concerning the absence of analogy between the ancient and modern state of our planet. A close comparison of the recent and fossil species, and the inferences drawn in regard to their habits, accustomed the geologist to contemplate the earth as having been at successive periods the dwelling-place of animals and plants of different races, some terrestrial and others aquatic, some fitted to live in seas, others in the waters of lakes and rivers.

"By the consideration of these topics, the mind was slowly and insensibly withdrawn from imaginary pictures of catastrophes and chaotic confusion, such as haunted the imagination of the early cosmogonists. Numerous proofs were discovered of the tranquil deposition of sedimentary matter, and the slow development of organic life. If many writers, and Cuvier himself in the number, still continued to maintain that 'the thread of induction was broken,' yet in reasoning by the strict rules of induction from recent to fossil species, they in a great measure disclaimed the dogma which in theory they professed. The adoption of the same generic, and in some cases even of the same specific, names for the exuviæ of fossil animals and their living analogues, was an important step towards familiarising the mind with the idea of the identity and unity of the system in distant eras. It was an acknowledgment, as it were, that part at least of the ancient memorials of nature were written in a living language. The growing importance then of the natural history of organic remains may be pointed out as the characteristic feature of the progress of the science during the present century. This branch of knowledge has already become an instrument of great utility in geological classification, and is continuing daily to unfold new data for grand and enlarged views respecting the former changes of the earth. When we compare the result of observations in the last fifty years with those of the three preceding centuries, we cannot but look forward with the most sanguine expectations to the degree of excellence to which geology may be carried, even by the labours of the present generation. Never perhaps did any science, with the exception of astronomy, unfold in an equally brief period so many novel and unexpected truths, and overturn so many preconceived opinions. The senses had for ages declared the world to be at rest, until the astronomer taught that it was carried through space with inconceivable rapidity. In like manner was the surface of this planet regarded as having remained unaltered since its creation, until the geologist proved that it had been the theatre of reiterated change, and was still the subject of slow but never-ending fluctuations. The discovery of other systems in the boundless regions of space was the triumph of astronomy to trace the same system through various transformations—to behold it at successive eras adorned with different hills and valleys, lakes and seas, and peopled with new inhabitants, was the delightful meed of geological research. By the geometer were measured the regions of space and the relative distances of the heavenly bodies—by the geologist myriads of ages were reckoned, not by arithmetical computation, but by a train of physical events—signs which convey to our minds more definite ideas than figures can do of the immensity of time."

Geology is distinct from cosmogony. The history of the successive phenomena happening on a planet revolving round an orb of light and heat may be treated without reference to the condition of the same material particles while they were subject to entirely different conditions. Yet as in tracing the progress of a colony reference may often be made with advantage to the previous history of the same people in another region of the globe, so, in prosecuting geological science in a just and liberal sense, it is advisable to take into account the discoveries of collateral science, so far as these tend to give sure indications of, or even to fix certain limits to, speculations concerning the origin of the planetary masses.

For the successful prosecution of this inquiry geology must appeal to two entirely distinct branches of collateral science, chemistry, and astronomy; which indeed agree in this, that they are both directed to the elucidation of the properties of material substance; but the former is occupied with a study of its elementary constitution, the latter contemplates the relations of its congregated masses.

Chemistry, by analysis of the different sorts of matter visible near the surface of the earth, teaches us that almost everything is of a compound nature, and formed by the union of two or more elementary particles, endowed with distinguishable properties, and capable of a separate existence and of entering into new combinations. When thus freed from their combinations by processes of art the elementary particles or atoms, of the same kind, form, when reunited, solids, liquids, or gaseous expansions, according as they are affected by temperature, pressure, and perhaps other less general influences. Oxygen, the most abundant of all the elementary substances yet discovered, expands immediately on being freed from union with solid bodies, to a gas which occupies 2000 times the space it previously did; and as nearly half the ponderable matter of the globe consists of oxygen, we must admit, as a plain consequence of this analysis, that upon a general resolution of the compound rocks and minerals into their constituent elements, nearly half the weight of the exterior parts of the globe would expand into gas, and augment the atmosphere till the accumulated pressure should liquify the gas, or prevent further decomposition. What happens to free oxygen with the temperatures and atmospheric pressures which now prevail at the surface, would (we know by trial) happen to chlorine and other substances similarly released from combination, under other temperatures and pressures. As these conditions are now variable, and may be supposed to have passed through all possible grades, it is not improbable that all the substances which exist in the crust of the globe might be converted into gaseous expansions if freed from combination. The great antagonist force to the concentration of matter is heat; by augmenting this agent some substances are decomposed and the parts rendered volatile; in other cases combinations take place which are also volatile; and there are others in which gaseous substances combine with solids at particular temperatures only. Now, as the substances known in the outer parts of the globe are about 60 in number, as they all separately stand in different relations to heat, pressure, electricity, &c., it is conceivable that under particular conditions the mutual forces of the various particles might be so arranged, and so balanced by the influences of heat and other general conditions, that all sensible solidity and liquidity should vanish, and the whole globe dissolve into an expansion, where the particles would be, if not all free, yet in very different combinations from those we now see. This is conceivable as an hypothesis, and chemistry can teach us no more; for as we have not ascertained for each substance, taken singly, what must be the conditions for its appearance as a solid, liquid, or gaseous body, nor have the means of computing what variation in this respect might result from particular admixtures of the substances, it is impossible to deny that the hypothesis may be true, and it would be equally unphilosophical to assert that it is. In this dilemma we must turn to the contemplation of phenomena which may serve to guide us to a just decision. Omitting for the present all considerations of geological phenomena, we must accompany the astronomer in his survey of space, in order to discover if any masses of matter exist which are of the nature of the gaseous expansion assumed; if this be the case, we must further inquire if there be gradations in the appearances they present such as to justify the belief in the possibility of a gradual conversion of a planet into an expansion, or the contrary. To these inquiries the far-seeing eyes of Herschel supply a positive answer. Through various parts of the heavens are scattered large expansions of attenuated matter, called nebulæ, which are irregularly reflective of light, various in figure and degree of condensation. The latter circumstances being carefully studied, it appears that many of them are of a globular or elliptical figure, as if the parts were collected by a general attraction toward a centre; that others in addition, appear to grow continually denser toward a centre, while not a few objects show in the centre the brightness of a solid star surrounded by a thick and extensive haze. Occasionally two or more points of condensation appear in a nebulous mass, thus affording a great analogy with what may be supposed to be the origin of our planetary system.

Comets, which are to be regarded as nebulæ attracted to some one or more systems, supply another and strong analogy with orbitual planets. But it may be reasonably expected that in addition to the graduated appearances of expansion, condensation, and nebulous solidity, there should be proof of corresponding gradations of density. This proof, as far as relates to the nebulæ far distant from our system, can perhaps never be given, though appearances are in favour of the view; even with respect to the comets which enter the solar system, further researches must be made; but the planets themselves supply such a proof, for their density varies exceedingly. The planets nearer to the sun are denser than those farther removed; Mercury, being the heaviest, is almost thrice as dense as the earth, while Jupiter, one of the distant orbs, is about one-third as dense as our earth; and Saturn, which, excepting Uranus, is the most remote, is only one-eighth or one-tenth as dense, and may be considered as light as cork. (Herschel, 'Introduc. to Astron.,' p. 278.)

Finally, this general idea of the origin of the mass of the earth from a nebular expansion, suggested by chemical facts, and supported by the appearances in the visible heavens, is confirmed by the mathematical researches of Laplace, who has by this supposition connected together the most striking phenomena of the solar system; the general parallelism of the orbits of the planets, the consentaneous direction of their movement round the sun, of the satellites round the planets, the anomaly of Saturn's ring, and other important circumstances. We have therefore only one test more to which the hypothesis can be subjected, namely, its accordance with what is known of the actual constitution of the earth. This is still no question of geology, but of astronomy. It appears however very certain that neither the figure of the earth, which is that of a spheroid of revolution on its axis, nor the density of the earth, which is greater toward the centre than at the circumference, and so arranged that the surfaces of equal density are symmetrical to the axis of figure, are at all opposed to the doctrine in question, but rather confirm it. From astronomical and chemical considerations, then, it is probable that the mass of the earth once existed as a part of a diffused nebula, like some now visible in the heavens; and as no merely geological evidence as to the changes operated on the condensed planet can be of the smallest value in a question relating to the condensation of a nebula, we must adopt the conclusion as a limiting condition of geological theory.

But however firmly we may admit the truth of the speculation of the condensation of planets from a nebular expansion, it can now have but little influence on the progress of geology. For it cannot be employed as the origin of deductions which might disclose circumstances hidden from observation in deep parts of the earth, and explain complicated facts visible at the surface; and this for want of adequate knowledge of the successive effects which must happen among the elementary particles or masses of a nebula during its condensation, as well as of the necessary consequences which such effects must entail on the physical conditions of a planet.

There is however one point of importance which this speculation, if adopted, may assure us of. The condensation of nebulæ is gradual; the density of planets various the larger ones in general having the least relative weight; the earth must therefore be supposed to have passed through a long range of condensation; and this implies a continual change of intensity among some at least of the physical agencies which belong to it. Whatever was the antagonist force to the central attraction of the nebular mass, the gradual decline of this force must have been felt, more or less, by all the natural agencies related to it by opposition or sympathy. Even the extraneous influence of light is not independent of the change of conditions produced.

The continual condensation of the mass of a planet necessarily brings with it a change in the relative intensities of the agencies at work among its parts, because they operate under continually varying conditions. Some would lose and others gain in strength, and thus the aspect of the earth must have been continually changing, or subject to periodical renovation. By those geologists who accept the doctrine of the earth's continual condensation, from whatever cause, the uniform intensity of natural agencies taken separately, the continual compensation of their antagonistic effects, and the production of equal effects in equal times, must inevitably be rejected.

Yet though, in strictness, the preceding reasoning forbids assent to Sir Charles Lyell's general principle, that the former changes of the earth's surface "are referrible to causes now in operation," it by no means follows that other causes (that is, other combinations or measures of natural agencies) than those now in operation must be appealed to for explaining the monuments of past revolutions of nature which are preserved to our days. For if these monuments go but a short way back on the scale of time, compared with the periods which elapsed in the condensation of our planet, the causes may not have sensibly varied during the whole course of phenomena traceable in the crust of the earth. This must be decided by a study of the monuments themselves, upon the general and acknowledged principle that effects are proportional to the causes. Still less is it to be imagined that the study of the effects of modern causes in action is unfruitful in illustrations of the phenomena due to ancient causes; on the contrary, there is no other way of learning either the kind or degree of physical agencies concerned in geological operations of early date than the comparison of these with the results of the daily action of the modern powers of nature.

The knowledge of the condition of the earth with respect to temperature is one of the most important steps which can be taken toward a right general contemplation of the history of the revolutions which it has undergone. This knowledge cannot be gathered by geologists labouring as such; it cannot be obtained by meteorological observations, however accurate; nothing short of a mathematical theory of heat, supported by a variety of data concerning the physical constitution and relations of the earth to the sun and space, will be at all available in grappling with the inherent difficulties of the subject. For this theory we are indebted to Fourier.

The heat of any point on the surface of the earth regularly varies, from hour to hour, with the rotation of the globular mass on its axis; from day to day and from season to season, with its revolution round the sun; and from year to year, with any change in the dimensions or form of the earth's orbit. There are however several causes of irregularity or fluctuation of temperature not demanding notice in a general view.

If in its long course round the sun the earth passed through parts of the planetary spaces of unequal temperature, this would cause a modification of the periodical, annual, and daily variations.

The atmosphere and the ocean by their various movements modify all these circumstances, but not so as to disguise the results when an average of many periods is taken.

In consequence there is for each point of the earth's surface a certain mean temperature, depending on the causes above stated; and the parts under the surface continually tend to acquire very nearly the same temperature as the surface, but not at the same time. The extremes of summer heat and winter cold are not felt till after they have passed away from the surface; and in proportion as we descend, the influence of the daily, monthly, and annual variations grows less and less, because of the slowness of the conduction of heat through earthy substances.

At a certain depth below the surface these variations become wholly insensible, and the temperature is constant, and nearly the same as the mean temperature of the surface.

If the temperature of the interior parts of the earth be now very different from that constant heat which would result by communication from the surface (heated as before, and subject to the stated variations), this difference would exercise a corresponding though insensible effect on the surface heat, and be more or less sensible at small depths below the inner surface of constant temperature.

Whatever may have been the proper or original temperature of the inner parts of the earth, it is easy to conceive that in a very long time the equilibrium of heat should be reached, and the earth receive from the sun and radiate into the ethereal space equal quantities of heat in equal times; while the temperatures at points situated at very great depths below the surface (many miles, for instance) would not sensibly vary from that of the mean heat of the place vertically above them.

But if this equilibrium be not attained, the original state of the earth as to heat may be ascertained, so far as to determine positively whether it has formerly been hotter or colder than at present, by merely trying at many points exempt from volcanic action, what is the amount of heat at various depths, on the same or different vertical lines, as compared with the corresponding points of surface.

These trials have been made at various depths, under different circumstances, in salt-pits, coal-works, and mines of different metals, in the British Isles, France, Germany, Mexico; and in all situations where the external influence of the air and the artificial effects of light, respiration, &c., could be guarded against or justly appreciated, they agree in proving that after descending below the limit of variable heat, a continual augmentation of temperature constantly occurs. (1° Fahrenheit for 15 yards is a common ratio.) The mine of Fahlun, supposed to be an exception to this general truth, is extremely ill-suited for experiments. (See Thomson's and Clarke's 'Travels in Sweden.')

The consequence is obvious. The interior masses of the globe are incomparably hotter than the parts at the surface; must formerly have been still hotter; and though now the interior heat is almost wholly masked and stifled by the non-conducting stratified masses which form the crust of the earth, it must formerly have influenced in a decided manner the temperature, and with it all other phenomena at the surface of the earth.

The same conclusion as to the existence of great heat in the central parts of the earth has been drawn from considerations of the density of the interior masses as compared to the superficial parts. While the surface rocks are twice and a half as heavy as water, the mean density of the whole globe is five times as great as that of water; moreover the density augments towards the centre with so much of regularity, that the imaginary interior surfaces of equal density are symmetrical to the same centre and axis as those of the exterior spheroid. (Conybeare's 'Report on Geology to British Association,' 1832.) Now, if the interior masses of the earth are compressible even to a far less extent than the rocks near the earth's surface, the pressure to the centre would have made the inner parts much more dense than they are: the whole mass of the earth would have been included in a much smaller volume were it not for some antagonistic force, such as heat is known to be. Unless therefore we venture to suppose the central and surface matter not subject to similar laws of force, it must be admitted that the interior parts of the earth are still very hot.

This great truth established, we may inquire further into the state of the interior masses. If the heat of the globe were increased its diameter would be augmented; there is a degree of heat which would liquefy nearly all the substances of which it consists, taken singly, and still more easily when in their usual combinations. Beyond this degree of heat gaseous compounds would mix with or altogether replace the liquid rocks, and the globe would be lost in a nebulous expansion.

Turning to observations of phenomena, we find the interior rocks to be such as were cooled from igneous fusion: they are extensively, perhaps universally, spread below our feet; and thus we gather the conviction that originally the whole or great part of the exterior masses of the planet were in a melted state. The figure of the earth is such as would result from revolution on its axis, provided the whole or a very large part of the mass were in a state of fluidity or viscidity; to this figure the surfaces of equal density correspond both as to centre and axis; and thus strongly corroborate the speculations of Leibnitz, that the earth is to be looked on as a heated and fluid globe, cooled and still cooling at the surface by radiation of its superabundant heat into space.

To determine whether it is now solid or partially fluid within is a problem of high interest, and one which we may perhaps despair to see completely solved, unless certain astronomical phenomena (precession, nutation) should be found, when analysed by a rigorous mathematical deduction, to furnish interpretations which geology alone can never attain to. As however Mr. Hopkins has presented some simple views of the possible conditions of a cooling globe (as the earth may be considered), we shall here briefly state them.

If the earth were originally a hot fluid mass cooled by radiation, the cooled parts would descend towards the centre, and be replaced by others in a perpetual circulation. The tendency to solidification in such a mass would be directly as the pressure, inversely as the temperature, both which are at a maximum at the centre: solidification would therefore be determined near the centre by the superiority of pressure over temperature; and at the surface by the rapidity of external refrigeration overbalancing the internal conduction of heat. The numerical relations of these qualities are unknown. It cannot therefore be decided by mere calculation whether the solidification of the surface by radiation would precede or follow that of the centre by pressure. Let us suppose, for simplicity, the relations of pressure, heat, circulation, conduction, and radiation to be such that all the mass goes on cooling till every part of its fluidity is lost, and the whole is reduced to such a degree of viscidity as to prevent the circulation of heated matter, the further distribution of heat must, under these conditions, be determined by conduction and radiation only; a large part of the interior would assume equality of temperature: the solidification of the surface by cooling would be the first new phenomenon, to be immediately followed by condensation through pressure about the centre; and thus two solid masses would be produced and continually augmented—a spherical nucleus, and a spherical shell—while between them would remain a large but diminishing zone of viscous matter, subject to some changes of temperature through the conversion of its surfaces from a liquid to a solid state.

If, on the other hand, the effect of pressure to the centre became superior to the expanding agency of heat, before the circulation of liquid matter had ceased in the superficial parts, the centre would solidify first; and the induration might proceed through a large part of the globe, so as even to approach the surface before that could be consolidated. If these conditions were reversed, consolidation might proceed from the surface downwards, and would ultimately reach the centre, and the whole mass be a stony globe.

It is important to remark that upon neither of these suppositions is it required to admit the continual augmentation of heat to the centre; to which M. Poisson objected, and instead of which he proposed to account for the phenomena of the earth's interior temperature, by supposing that the solar system had once passed through other ethereal spaces than those which it now occupies, and there experienced much higher temperature at the surfaces of the planets. This hypothesis may be perhaps not very different in its development from the more general theory of the nebulous origin of the planets; but it appears unnecessary to discuss the speculation after what has been said of the cooling of the earth.

We may now proceed to examine the modern causes of changes on the surface of the earth. The never-ceasing activity of the powers of nature may be viewed as an inextinguishable and unavailing effort to restore an equilibrium which is incessantly disturbed. The protean changes of the atmosphere; the varying effects which its chemical and mechanical energies occasion among the masses of dead matter and the forms of life; the flowing of the ocean; the subterranean fire and wide wasting of the earthquake, are all efforts to obtain rest consequent on a succession of perturbations. In this sense, not the earth only, but all the solar system, and perhaps all the extent of the heavenly spaces, conceivable rather than visible by man, is in the condition of instability described in the Pythagorean Philosophy, "Nihil est toto quod perstet in orbe."

These changes on the surface of the earth affect the geographical boundaries of land and water, the relative level of land and sea, and the forms, proportions, and distribution of animal and vegetable life. In a popular sense they may be classed by their proximate agencies, as depending on chemical and mechanical powers originating from atmospheric action, rains, springs, rivers, &c.; as depending on similar powers residing in the ocean; and as affected by volcanic forces. We may also venture to contrast the effects of the watery agencies, whether of atmospheric or oceanic origin, with the products of volcanic fires. For the general effect of the watery agencies is to abate the high and to raise the low, to equalise the level of land and sea by abrading the former and filling the latter; but volcanic effects are directly the reverse. They augment the original inequality of the surface; in some parts they raise matter from within the earth, and form new hills to bear the ravages of the atmosphere; and elsewhere cause tremendous depressions of land, and sink in deeper hollows the original basins of the ocean.

The external influences, thus contrasted with the interior powers of the globe, are far more various in their aspect and more general in their visible operation; yet they may all be reduced to one or two variable forces, independent of the terraqueous system. It is to the unequal accession of heat from the sun, upon a globe whose distance varies, whose parts are variously presented to the radiating beams, and to the unequal abstraction of heat by the cold ethereal spaces in which the earth circulates, that we may refer all the variations of corpuscular and mechanical phenomena on the globe; while in the varying diffusion of light we recognise the prime element of change in the animal and vegetable world.

Minute as is their momentary impression, the sum of their effects in a long time is prodigiously great; heat and moisture by alternate influence weaken; frost bursts; carbonic acid eats with cankering tooth; rains, swallowed up by the fissured rocks, abstract parts of their substance; land-slips, avalanches, and glaciers heap the valleys with detritus, till swollen rivers or bursting lakes sweep away the burden towards lower ground, or convey it even to the sea. Thus chemically dissolved, mechanically suspended, or roughly rolled along, the substance of all the rocks and mountains yields to a slow but sure destruction, and those who, adopting the notion that 'time costs nature nothing,' take as much of this as pleases them, may easily see, in the effect of these operations, the total disintegration of the existing continents and islands, which is so conspicuous a feature in Dr. Hutton's hypothesis of the decaying and renewing earth.

Nor is the sea less a theatre of change than the land. For, independent of its receiving the spoils of the land, and distributing them on its bed, the untiring agitation of its waves undermines the cliffs which are above its level, grinds away the rocks which are covered and uncovered by the tides, and distributes the materials in various ways, here making dangerous sandbanks, there adding to the low shores a valuable heritage.

Nor even below the deep water of the middle ocean is all at rest. There multitudes of sea animals, the Infusorial Animalcules, the Zoophytes, and Mollusca, by their mere exuviæ tend to fill up the depths; and certain tribes (the lamelliferous corals in particular), by their peculiar growth and mutual adherence form calcareous islands and reefs, similar in some important particulars to the ancient limestone rocks. These coralligenous rocks are however not reared from the extreme depths of the sea, but based on the summits of submarine hills, or the crests of volcanic cones, and thus, in a general expression, we may say that in modern nature most of the deposits of solid matter in the sea are joined to the shores or shallows of the previously formed land.

The sediments transported by rivers, and gathered by the wasting of the elevated coasts, being for the most part deposited along the sea-shores, and almost wholly below the level of high water, it is obvious that from this cause alone the bed of the sea is filling up, and its depth diminishing toward the shores; but as the quantity of water on the globe must be supposed sensibly constant, it follows that the oceanic area must expand, or its surface rise a little. But since the land is wasted by the waves, as we may suppose the augmentation of area which results from this cause sufficient to balance the elevating tendency of the littoral deposits of sediment, and that upon the whole the effect of the watery agencies on the globe is insensible in altering the level of the surface of the sea, as compared to the deeper parts of its bed; it follows, as a strict consequence, that the area of the ocean is enlarging. This appears also probable from observation; for the small addition of marsh-land on particular shores, by the influence of rivers, winds, and storms, in raising littoral sediments above the reach of all but the extremely high tide, is not enough to balance the continual waste of land along many thousand miles of perishing cliffs. By the mechanical agency of water considered alone, the land is certainly losing in area continually. The accumulation of marine exuviæ on the bed of the sea acts in the same direction, and the growth of coral principally concurs in the same result. Left to watery agency alone then the land may be imagined to be continually diminishing, as Dr. Hutton and Sir Charles Lyell suppose. If the shores of the sea did not waste away, the annual additions of sediment brought from the uplands would everywhere cause the water to rise in level; if the land were supposed to overhang its base at a certain angle depending on the diameter of the earth, the area of the ocean would remain invariable; but as neither of these conditions applies, it is certain that the area of the ocean is extending, and probable that its level does not materially change.

Volcanic phenomena, the earthquake, and the ignivomous mountain, are to be viewed as cases of critical action. Whether the heat of the interior of the globe be the residual portion of its original temperature (chaleur d'origine of Arago), or generated by the access of water, or other bodies containing oxygen, to certain chemical substances, it is to the disturbance of its equilibrium that the violence and the tumult of volcanic excitement are owing. But there are other and more gradual effects of the distribution of heat in and upon the globe which require notice. The most important of these is the gradual change of level of certain parts of the land, as compared with the general level of the ocean, one instance of which is supposed to occur on the shores of the Baltic, where certain tracts appear to be slowly rising above the sea. (Lyell, in 'Philosophical Transactions,' 1835.)

Concerning this 'secular inequality' (as it may be termed), of level of land and sea, it is unfortunate that nothing at all important is known towards determining the important question whether the elevation of one tract of dry land or sea-bed is balanced or overbalanced by the depression of another. Lyell assumes that the depression of land from this cause exceeds the elevation, but it is difficult to find sufficient evidence for this important postulate; and to adopt it merely as a consequence of another unproved assumption of a continual compensation of the agencies of nature is altogether inadmissible.

If there be in the earth a pervading high temperature, which diminishes from the interior toward the surface, in consequence of the radiation from the surface, it appears from Sir John Herschel's reasoning (given in Mr. Babbage's 'Ninth Bridgewater Treatise') that along the shores of the sea the isothermal lines of the interior of the globe should rise, because of the continual deposition of imperfectly conducting sediments there. For thus the radiation of heat along these lines would be diminished until the interior heat had come nearer to the surface. By the consequent expansion of the subjacent earthy substances the sea-shore should rise, and thus the addition of sediment from watery action, and the effect of the effort to restore equilibrium in the disposition of the interior temperature would, upon the whole, coincide in minutely raising the surface of the sea.

It is chiefly near the sea-coast, on the land or in the ocean, that volcanic phenomena are at this day seen in activity, and this apparently because the admission of water to some depth below the surface is necessary to the excitement of the imprisoned forces of heat. The elevated cones and large areas of melted rock, or accumulations of scoriæ and ashes, mark one of the prevalent effects of the volcanic forces to be the withdrawal of matter from the interior to heap it on the surface of the earth. But the cavities left by this operation below the crust of the earth must often cause depression of masses of land during the concussion and displacements occasioned by earthquakes. In this manner it may easily be understood that the volcanic islands of the South Seas have been raised up from the sea-bed there, and it may be supposed that under large tracts of the ocean volcanic agency is employed in a similar way, and by a superiority of elevation over depression raising irregularly the bed of the sea, and by consequence extending the area of its surface. If all the cavities left below the surface by the heaping of volcanic matter on the land were completely balanced by corresponding depressions of the crust of the earth it would depend upon the proportion of submarine subsidence corresponding to terrestrial elevation whether the sea-level should fall and its area contract. Every sinking of the sea-bed corresponding to an elevation of the dry land would tend to lower the level of water and to augment the area of land. Along sea-coasts such correspondence must be admitted occasionally to occur. If the cavities alluded to were not compensated by the sinking of the superincumbent crust volcanic pheuomena on the land would hardly affect the area or level of the sea; but similar eruptions in the sea would raise its level and cause it to encroach upon the land. If it be admitted as the most probable basis of reasoning whether subterranean cavities exist or not, that the continual elevation is upon the whole balanced by continual subsidence, submarine and continental volcanic vents may be left out of consideration; but the littoral and insular volcanoes act in one certain way, and give as the general result of all volcanic action a partial deepening and a general contraction of the sea, which counterbalances in kind the general effect of the aqueous agencies; but whether these completely antagonist principles are equal in degree cannot be safely inferred from any data now accessible to geology. Nor does it appear prudent to rest so important a conclusion on the mere fact of the constancy of the earth's dimensions, indicated by the invariable length of the solar day; the experience of 2000 years is as nothing in a question of such infinitesimal differences of diameter as might be occasioned by changes in the relative position of the really small quantities of matter raised or sunk by volcanic powers.

Moreover it is impossible to avoid doubting whether even the quantity of water on the globe is constant; for so many combinations of earthy substances require certain proportions of water for their completion, and so much of volcanic excitement appears due to the decomposition of water, that it would perhaps be safer to suppose the water continually diminishing in quantity; nor is it at all unlikely that such may be the case with the atmosphere.

The question of the comparison of the effects of natural agencies in modern and ancient times is one of considerable importance in relation to geological enquiries.

The statement of the effects of modern causes must necessarily be received as true and applicable to other eras of the world, at least in its general features; because the chemical, mechanical, and vital forces of nature are admitted as individually constant, though their manifestations to our senses be ever so various in kind or degree, in consequence of change in their combinations, the quantities of matter operated on, external influences, &c. Fixed laws and variable conditions are certainly recognised in existing nature, and they give rise to extreme inequality in local results and combinations. It is conceivable, by extending this idea, that the existing laws of nature should be productive not only of results which, taken locally or periodically, appear unequal in degree or diverse in kind, but that under the influence of a general change of conditions they should manifest a gradual decay or increase of strength, or spring into extraordinary activity after long periods of apparent slumber. Let, for instance, the sun's rays be supposed to fall upon the earth in smaller quantity through the augmentation of the minor axis of the earth's elliptic orbit; let the temperature of the ethereal spaces rise: who does not see that all the effects depending on the external excitant forces would immediately change? In like manner let the earth's internal energy of heat be supposed to die away, whether for lack of fuel, incrustation over metalloids, or a loss of general warmth in the globe, the volcanic phenomena would be weakened, and no longer balance the effects of water.

Now, as these great conditions cannot be affirmed to be constant, but, on the contrary, as one at least of them is known to be variable (the earth's orbit), how "baseless as the fabric of a vision" is the assumption that the physical agencies on the globe have always produced "equal effects in equal times," and that modern causes acting with their present intensity have produced all the older phenomena of geology. But it would be equally unjust, as observed before, to assume that they have not; the question, if capable of determination, can only be settled by ample observation and logical induction.

Among the ancient phenomena of nature we equally recognise the contrasted action of water and heat, as at this day: by the former the solid land was wasted, and stratified rocks were deposited along the sea-shores (as sandstones) and in the depths of the sea (as some limestones), while the latter manifested itself in the production of unstratified crystalline rocks, and the elevation and disruption of the stratified bed of the sea. [ROCKS; STRATIFICATION.] The materials arranged by the action of water in the stratified rocks of ancient date are the same as those now carried by rains, suspended by the tide, or separated from sea-water by the vital functions of invertebrata; they are, to a certain extent, similarly associated: the organic exuviæ buried in them are not very differently arranged or grouped from those which now lie in the bed of the sea (Donati's 'Researches on the Bed of the Adriatic' may be quoted in proof of this); the physical conditions of their accumulation were therefore in a considerable degree similar.

On a careful consideration of the facts, it appears obvious that the long series of stratified deposits was not accumulated without great and even sudden changes of those physical conditions: thick deposits of sandstone are followed by others of clay or of limestone, for which different agencies and conditions were required. Over the same spherical area of the earth's surface the predominant physical conditions varied from time to time, and many times, so that the actual state of the globe, as far as regards watery agencies, represents not all its previous conditions, but is to be compared with each of them successively. The same is true of the igneous products in the crust of the globe, which similarly varied from time to time in the same spherical area.

Successive phases of the aqueous and igneous agencies over the same region appear, either contemporaneously or successively, to have affected all parts of the earth's surface accessible to man; so that everywhere there is proof of great revolutions in the condition of land and sea. Moreover it appears [ORGANIC REMAINS] that to each general system of stratified rocks, indicative of a corresponding great system of physical agencies, peculiar races of plants and animals belong:—with new physical conditions new forms of life came on the globe, vanished with those conditions, and gave place to others equally transitory. If now we compare the modern survey of nature with any similar work, executed on the same principle, for any one of the earlier epochs, it is certain that the earth has undergone many very extensive revolutions in all that respects its aqueous, igneous, and organic phenomena, before arriving at its present state: it is equally certain that between the epochs of these revolutions the state of the earth was not extremely dissimilar to that which we now behold; yet, because the organic beings preserved in the earth in each of these systems are peculiar to it, and differ from the others, and from those that now live, we cannot possibly doubt that the points of difference were numerous, general, and important.

To determine the cause of the change of physical conditions between one system of stratified rocks and another is not difficult. In existing nature such a change might be easily produced in almost every region by a disturbance of the level of some particular tracts of land, by one great movement or many successive displacements. For example, let the Isthmus of Suez or the Isthmus of Darien sink one hundred or a few hundred feet (perhaps scarcely beyond the range of the power of an earthquake), what mighty changes would be occasioned in the Indian, Mediterranean, Atlantic, and Pacific Oceans, over areas which would appear considerable even when compared with many ancient systems of strata—changes of stratified deposits and physical conditions, and consequent variations in the relative abundance and geographical distribution of organic beings. Now, though at this day no such mighty changes are witnessed, we have only to enlarge our conception of the actual effects of volcanic agency to see clearly that this is the power which was employed in producing them.

The analogy of the effects of aqueous and igneous agencies in all past periods of the earth's history being assumed, we may proceed to gather inferences as to the measure of the intensity with which they have operated, and the time which has elapsed during their operation. This requires at least a brief summary of the characteristic features of the phenomena of successive steps of the earth's formation, in the order of their occurrence. Observation can only guide us to a knowledge of the crust of the earth for a depth of a few miles at most; and from what we there behold it is probable that a much greater extension of the power of observing would really help us but little in tracing the history of the revolutions of our globe of which monuments remain for inspection. For at some moderate depth below the surface all marks of lamellar increase, indicative of periodical formation, cease; all monuments of life and watery action terminate; and we behold the effects of heat alone. The general basis of all the crust of the earth, in which we trace the combined results of igneous, aqueous, and vital energies, is a mass of crystallised rocks, the fruit of great and very general heat; which limits all inquiry in that direction.

From the surface of these interior crystalline rocks, mostly of the nature of granite, the monuments of physical changes left in the rocks are capable of interpretation by the application of the knowledge we have gathered of chemical, mechanical, and vital forces, but below it all appears at first sight dubious and dark. Were these rocks of igneous origin anterior to the whole crust of the earth now placed upon them? Or does the interior heat slowly reconvert to granite the masses of sedimentary strata laid upon it by external watery agencies? In the former case the monuments of nature are complete so far as any thing analogous to the present system of surface agencies is concerned; but according to the latter supposition, the earlier strata, with whatever of organic exuviæ lay in them, have been reabsorbed and melted into the hidden secrets of the earth, and a similar fate awaits their successors.

To assume the truth of either of these views is altogether contrary to the prudent spirit of modern philosophy: no inspection or analysis of the old granitic masses; no merely analogical comparison of them with the fluid compounds of existing volcanoes; no à priori reasoning will solve the question. Yet it appears capable of solution by a full and impartial consideration of the stratified crust of the earth itself, which ought to show in the nature and condition of the lower strata as compared with the upper, and in the nature and abundance and mode of conservation of organic remains, evidence not only of the circumstances under which they were accumulated, but indications of the nature and extent of the changes which have since occurred to them. This mode of inquiry we shall endeavour to follow.

This first diagram is intended to show how very small is the supposed depth of the crust of the earth, and of the most profound parts of the ocean, compared to the radius of the globe. The thickness of the crust of the earth, here taken at 15 miles, is perhaps on a general average not so much as 5 miles. To this mere film on the surface of the globe Inductive Geology is confined; though by help of collateral science we have learned many truths as to the constitution of the hidden interior masses.

The difference of the diameters of the earth is nearly 26 miles. If the axis of the globe were displaced 90 degrees, the level of the sea would rise at the old poles and sink at the new poles about half that quantity, or 13½ miles; and at other points intermediate quantities, according to their relations to the great circle passing through the new and old poles of rotation. At the poles of this great circle there would be no alteration of level.

By imagining the depth of 1000 miles, in the first diagram on the following page, to be repeated three times, and the three radii to be at the same time prolonged till they meet at a point, which would represent the centre of the earth, the reader will easily form a notion of what is intended.

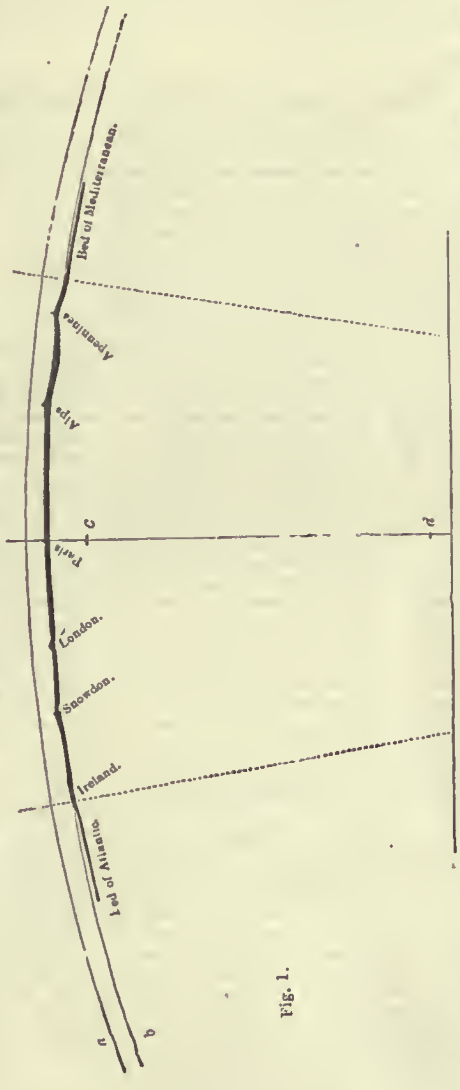


Fig. 1.

a, line representing the supposed limits of the atmosphere, 45 miles above the earth; *b*, level of the sea; *c*, depth of 100 miles on the radius, the black part being the supposed thickness of the earth's crust; *d*, depth of 1000 miles.

The arc includes 20 degrees from the Adriatic to the Atlantic, passing over the Apennines, the Alps, the English Channel, the Welsh Mountains, and the Irish Sea, the depth of the narrow seas being less than the breadth of the fine lines.

Fig. 2.—A general section of the crust of the globe, about 100 miles in length and one mile in depth, from Bridlington, B, to Whitehaven, W, on a true scale, that is, the height proportioned to the distances. G, the granite, appearing under the slaty primary rocks, P, of Cumberland, which rise to the height of 3160 feet; C, the carboniferous system, rising to the height of 2901 feet in Crossfell; R, the red-sandstone, or saliferous system, usually found in very low ground; O, the oolitic system, rising to 1485 feet in the Hambleton hills; Cr, the cretaceous system, which, at its highest point in the York Wolds, is 805 feet above the sea; *d*, dykes of basaltic or porphyritic rock; *f*, a great dislocation.

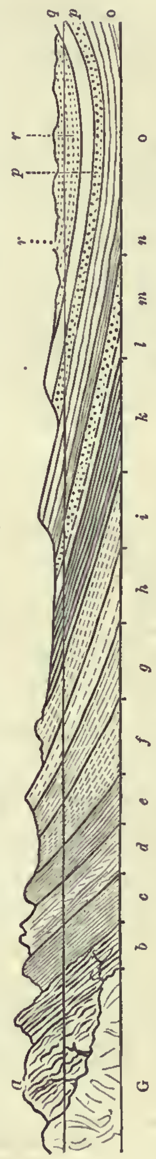

Fig. 3.—General view of the succession of British strata, with the elevations they reach above the level of the sea.

G, granitic rocks; *a*, gneiss; *b*, mica schist; *c*, Skiddaw or Cumbrian slates; *d*, Snowdon rocks; *e*, Plynlymmon rocks; *f*, Silurian rocks; *g*, old red-sandstone; *h*, carboniferous limestone; *i*, millstone grit; *k*, coal-measures; *l*, magnesian limestone; *m*, new red-sandstone; *n*, lias; *o*, lower, middle, and upper oolite; *p*, greensand; *q*, chalk; *r*, the tertiary strata.

The general section (*fig.* 3), combined with the complete table of British strata which follows (extracted from Phillips's 'Guide to Geology') will serve for reference to the reader who may be unacquainted with the arrangement of the stratified rocks in the crust of the earth.

Series of British Strata, beginning at the Surface, from which all Water-Moved Gravel and River Sediments are supposed to be removed.

The Marine Strata are marked by Figures; the Fresh-Water and Æstuary Beds by Letters; the names of some characteristic Fossils are in Italics.

TERTIARY STRATA.

(A small number of the Fossils are identical with existing species.)

Names of Formations.	General Thickness. Yards.	Remarks.
1. Clay	16	A water-drifted mass of marine shells, pebbles, &c., resting on more regular shelly beds of sand or sandy limestone. About 40 per cent. of the shells are supposed to be identical with existing species.
a. Fresh-Water Marls	33	They include a bed of æstuary shells, and occur only in the Isle of Wight.
2. London Clay	100 to 200	Mass of clay rich in marine shells, of which $3\frac{1}{2}$ per cent. are identical with recent kinds.
2. Plastic Clay	100 to 400	Variously coloured sands and clays, the latter containing organic remains identical with, or much allied to, those of the London clay.

SECONDARY STRATA.

(All the Fossils belong to extinct species. They are different from those in the Tertiary Strata.)

System.	Names of Formations.	General Thickness. Yards.	Remarks.
Cretaceous System.	3. Chalk	200	Of unequal hardness, soft above, marly below, with interstratified flints; extinct *Zoophyta*, *Ananchytes*, and other *Echinodermata*.
Cretaceous System.	4. Greensand	160	Upper Greensand, very fossiliferous, in general chalky. Gault, a blue marl, or clay, often very fossiliferous. *Belemnites minima*. Lower greensand, or iron-sand, very fossiliferous in places.
Oolitic System.	b. Wealden	300	Weald clay, with fresh-water shells. *Cyprides*. Hastings sands, with land-plants, and bones of *Iguanodon*. Purbeck beds of clay and limestone, with fresh-water shells.
Oolitic System.	5. Portland Oolite	130	A variably locally oolitic limestone; some beds full of fossils. Kimmeridge clay, with layers of *Ostrea deltoidea*.
Oolitic System.	6. Oxford Oolite	150	Upper calcareous grit. Coralline oolite, with beds and masses of coral; *Echinida*; many shells. Lower calcareous grit. *Ammonites catena*, *Pinna lanceolata*. Oxford clay. Kellaway rock. } *Ammonites Calloviensis*, *Gryphæa dilatata*.
Oolitic System.	7. Bath Oolite (near Bath)	130	Cornbrash, thin, impure, shelly limestone. *Avicula echinata*. Forest marble. Shelly oolite, with concretionary sandy limestone. Bath oolite. In several divisions, shelly, oolitic, compact, and sandy beds. *Megalosaurus*, *Apiocrinus*. Fullers'-earth. A series of calcareous and argillaceous shelly beds. Inferior oolite. *Pholadomya*. *Trigonia striata*. Sand, with concretionary masses holding shells.
Oolitic System.	8. Lias	350	Upper lias shale. Full of characteristic saurians, of *Ammonites*, *Belemnites*, and other shells. Marlstone, replete with *Terebratula*, *Pectinida*, *Avicula inæquivalvis*. Middle lias shale. Contains *Gryphæa*, *Ammonites*. Lias limestone, with *Gryphæa incurva*, *Ammonites Conybeari*. Lower lias shale and coloured marls.
Saliferous, or New Red-Sandstone System.	9. New Red-Sandstone	300	Coloured marls, gypsum, and rock salt. Red and white sandstones and marls. Conglomerate and sandstone. } Few or no organic remains.
Saliferous, or New Red-Sandstone System.	10. Magnesian Limestone	100	Knottingley limestone. A few bivalves in the lower beds. Gypseous red marls. No fossils. Magnesian limestone. Shells, corals. Marl slate. Fishes of remarkable forms. Red-sandstone. Plants of the subjacent coal series occur in it.
Carboniferous System.	c. Coal	1000	The subdivisions of the coal series are only locally ascertained. Gritstone and shales constitute the principal mass. Flagstone and iron-stone are among the most characteristic layers. Fresh-water limestone and marine limestone are exceedingly rare and local. The shells are mostly of æstuary origin. The plants are mostly of terrestrial tribes and extinct genera.
Carboniferous System.	11. Carboniferous or Mountain-Limestone	800	Millstone grit, series of sandstone, shales, coal, and thin limestones, forming a transition group between the coal and the carboniferous limestones. Yoredale rocks, consisting of five or more beds of limestone, with alternating flagstones and other gritstones, shales, thin coal, iron-stone. Lower or scar limestone, in the north of England and Scotland, subdivided by sandstones, shales, and coal seams. They yield characteristic *Crinoidea*, *Productæ*, *Spiriferæ*, *Orthocerata*, *Bellerophon*, *Goniatites*. Alternating limestones and red-sandstones, forming a transition group between the carboniferous limestone and red-sandstone formations.
Carboniferous System.	12. Old Red-Sandstone	100 to 3300	Conglomerates and sandstones. No fossils yet noticed. Coloured marls and concretionary limestones, called 'cornstones.' A few fossils. Tilestones, or flagstone beds. A few fishes.

PRIMARY STRATA.

All the fossils belong to extinct species, and often to extinct genera and families. They are different from those in the Secondary and Tertiary Strata. It has been usual to class the upper systems under the title of Transition Strata, and to confine the name of Primary to the mica-schist and gneiss systems. The following view of the Silurian Strata results from Sir Roderick Murchison's researches:—

System.	Names of Formations.	General Thickness. Yards.	Remarks.
Silurian, Upper Grauwacke, or Transition System.	13. Ludlow Rocks	660	Sandstones. Species of *Orbicula*, *Lingula*, Terebratula, Spirifera. Limestone. *Pentamerus*, *Homonolotus*. Shale.
Silurian, Upper Grauwacke, or Transition System.	14. Wenlock Limestone	600	Limestone. Shale. } Corals and Crinoidea in vast abundance. *Euomphali*, *Producta depressa*, Orthocerata, *Calymene Blumenbachii*, and other Trilobites.
Silurian, Upper Grauwacke, or Transition System.	15. Caradoc Sandstone	830	Shelly limestone. Various sandstones. } *Pentamerus*, Terebratula, *Orthis*, Trilobites.
Silurian, Upper Grauwacke, or Transition System.	16. Landeilo Rocks	400	Calcareous flaggy beds, including *Asaphus Buchii*, and other Trilobites.

The stratified argillaceous rocks below, from the rarity of organic remains and other causes, are not so perfectly understood. The following arrangement, based on the labours of Sedgwick, is however correct, with reference to the succession of deposits in the Welsh and Cumbrian districts. The thicknesses are not exactly known.

Cambrian System.	17. Plynlymmon Rocks	Argillaceous indurated slate, sandy slates. No fossils yet found in it. Calcareous and argillaceous rocks, with *Orbicula*, *Zoophyta*, and other organic remains.
	18. Bala Limestone	Calcareous and argillaceous rocks, with *Orbicula*, *Zoophyta*, and other organic remains.
	19. Snowdon Rocks	Variously coloured and indurated argillaceous slate. A few fossils have been observed in Wales.
Skiddaw System.	Clay Slate	Soft dark slate. No fossils known.
	Chiastolite Slate	Soft dark slate, with chiastolite. No fossils known.
	Hornblende Slate	Soft dark slate, with hornblende. No fossils known.
	Mica-Schist System	No organic remains. The beds of mica-schist, composed of mica and quartz, alternate with gneiss, chlorite-schist, talc-schist, hornblende-schist, clay-slate, quartz-rock, and primary limestone.
	Gneiss System	No organic remains. The gneiss beds, composed of mica, quartz, and felspar, alternate locally with mica-schist, quartz-rock, and primary limestone.

Primary Periods.—Gneiss and mica-schist, two of the most abundant of the oldest stratified rocks, appear, as to their substance, to be composed of the same parts as granitic rocks, namely, felspar, quartz, and mica, with great variations of proportions, and some admixtures and substitutions of other minerals, constituting alike granite, gneiss, mica-schist, &c. But the ingredients are not in the same condition;—in the granite all are crystallised; each mineral is independently a crystal, or moulded in the cavities left between crystals; in gneiss and mica-schist the felspar, quartz, and mica are rolled or fragmented masses. The character of worn surface of the ingredients, combined with the lamination or stratification of the mass, assures us that aqueous agencies have determined the aggregation of gneiss and mica-schist: the character of the lamination, especially the minute flexures which abound in these ancient rocks, suggests somewhat of peculiarity in the condition of the water; and the internal crystallisation of the attrited felspar reveals its origin from the disintegration of granite.

On the other hand it has been contended that the similitude of the mineral composition of gneiss, or mica-schist, to granitic compounds argues a similitude of origin; and by some writers gneiss, mica schist, &c., are regarded even as igneous rocks; by others it is thought that gneiss and mica-schist are intermediate products between sandstone and granite, retaining the lamination and bedding which indicate their original aqueous origin, but assuming a new mineral composition in consequence of the agency of heat. Neither of these views appears satisfactory; to give a merely igneous origin to gneiss is evidently to leave out half the phenomena; to suppose the mineral composition of gneiss the effect of heat operating on a common sandstone will never be allowed by those who have studied the rock as it appears in Zetland, Scotland, or Norway; for in all these places it is clear that the granular minerals have not derived their external figure from concretionary but really from mechanical action, while their exterior structure is truly crystalline. There is however one mineral frequently found crystallised in gneiss and mica-schist, namely, garnet; and the history of this mineral leaves no doubt that the rocks in which it lies have been pervaded by a general high temperature, enough to affect such a fusible substance as garnet, but not enough to melt any one of the regular constituents of granite. Here then appears decisive testimony as to the degree of heat which the gneiss and mica-schist have experienced. By the operation of this pervading heat the particles of calcareous rocks associated with gneiss and mica-schist have undergone a great change: they have been converted to crystallised marble of various colours and qualities.

The arguments above advanced, conclusive as we deem them on the subject of the origin of gneiss generally, are not intended to apply to cases where, by reason of this rock being buried at great depths below the surface, extraordinary effects of heat may be experienced. There, no doubt, the gneiss such as we see it, clearly revealing the history of its formation, may be wholly melted and re-crystallised, so as to lose entirely all traces of its origin. Some such cases may occur, perhaps even we may admit that evidence for them exists in uplifted granitic regions; and thus some of the monuments of the earth's early history may have been lost: but that this cannot be the general rule almost every mountain-chain bears testimony.

In these, the most ancient rocks which exhibit to us the combined effects of aqueous and igneous agency, no traces of animal or vegetable life occur, and the conclusion we adopt on the subject is, that few or none of the organised wonders of nature were then in existence, because the physical conditions of the globe within which the existence of animals and plants is limited were not then established. Only one other view of the subject is worthy of notice. According to the hypothesis of the slow reconversion of stratified rocks to granitic compounds, the want of traces of organic forms in the gneiss and mica-schist is ascribed to the destroying agency of heat on the calcareous matter of shells, corals, &c., and the carbonaceous substance of plants. That heat will affect such calcareous and carbonaceous compounds in the manner assumed is certain. Perhaps it might be difficult entirely to reject the hypothesis in the case of the primary limestones, whose alteration to crystallised masses may be thought to have wholly destroyed the structure of the shells. Yet as in the limestone of Teesdale, similarly altered by contact with trap rocks, crinoidal stems retain their forms; and as near granite, trap, &c., vegetable remains are recognised, if not in substance, yet at least by their impressions in the shales or grits; and as, finally, among some rocks of the same mineral nature as gneiss and mica-schist, shells and plants of many sorts appear in the Col du Chardonnet in Dauphiné, the balance of evidence is decidedly against this extreme application of the theory of metamorphism of rocks.

Upon the whole then the evidence afforded by a careful examination of the oldest strata, in regard to their mineral composition, structure, and absence of organic remains, supports, we will not say establishes, the opinion that these are not only the most ancient strata which man can trace, but the oldest products of watery action on the globe, and in a great degree anterior to the origin of organic life.

The general results to which the study of the earliest systems of strata lead are these:—

1. They are the oldest aqueous deposits visible on the crust of the globe, and rest on masses which have received their present aspect from the action of heat.

2. They furnish no proof of the contemporaneous or previous existence of dry land.

3. They are equally destitute of evidence of the contemporaneous or previous existence of plants or animals in the sea.

4. The rocks of this ancient system are peculiar in their aspect, and though doubtless derived from disintegrated granite, &c., the constituent particles appear to have undergone much less attrition than those which compose rocks of later date.

5. These rocks are of such great extent as to approach nearer to universal formations than any of later date.

As a general inference, it appears that the circumstances which accompanied the accumulation of these rocks were greatly different from what we now behold, since nowhere on the sea-shores are any such products found, nor can we suppose anything analogous producible in the bed of the sea, unless where some peculiar agitation of water may hasten the disintegration of granite. The impression was very strong among early writers of the entire want of accordance between the causes of those early strata and those now in action. De Luc ('Lettre' iii.) more reservedly says, "We have no reason to expect that the operations of those times can be explained by specific analogies with what we observe in the present state of the earth."

And as one general hypothesis, we may say with the followers of Leibnitz and Fourier, that the proper internal heat of the earth was then only just so much reduced as to allow of a peculiar watery action upon its cooling crystallised masses, but not enough diminished to allow of the conditions within which the existence of organic beings is restricted on the earth.

This hypothesis is independent of the consideration already presented as to the original condensation of the globe, and cannot, we believe, be objected to on the ground of anything known concerning the present state of the interior of the globe; on the contrary, the temperature of the earth augments as we proceed downwards, and this fact, being general, has been shown by Fourier to be inexplicable except as a consequence of a general high temperature now existing in the earth. The planetary spaces round the earth are colder than any part of its surface (Fourier), and continually abstract heat from it: the globe is continually growing colder though at an insensible rate, and must have formerly been hotter, and then must have lost heat more rapidly. The obvious conclusion from the mathematical theory of the heat of the globe, coupled with observations of the temperature below the surface, leads to the adoption, as an inference from facts, of the view above proposed as an hypothesis to explain other facts. [Gneiss; Mica.]

Skiddaw, Cambrian, and Silurian Systems.—These argillaceous rocks of the primary series of strata bear the same relation to the gneiss and mica-schist as common clays bear to common sands in modern nature. Some clays are not really more distinct from particular sands in their mineral nature than in the comparative fineness of their constituent particles. In consequence of differences of magnitude and density, particles of clays and sands which are derived by watery action from the same sea-cliff, avalanche, or glacier, are soon separated, carried to unequal distances, and deposited in distant masses. Such, in many cases, is the true origin of the sandstones and shales of the secondary strata, and processes somewhat analogous may perhaps be supposed to have occasioned the remarkable distinctness and even reciprocity of occurrence of the gneiss and mica-schist on the one hand, and the slaty rocks on the other. It is seldom that both of these types of primary strata abound in the same geographical region, though there is little doubt that both are derived from a granitic basis. In some cases we may best conclude that the materials of the slaty rocks were obtained from the wasted gneiss and mica-schist.

Enormously thick as these argillaceous masses are, and extensive as is their geographical distribution, they offer in all countries a general character of aspect which easily arrests the attention and impresses the memory. The colour usually approaches to blue, gray, green, or purple; the texture is usually fine-grained, but portions are included not very different from sandstone or conglomerate (grauwacke, or clasmoschist of Conybeare); the structure is laminated and bedded more or less perfectly, and often in addition complicated with regular symmetrical joints; there is another entirely distinct set of such divisional planes called 'cleavage,' traversing the planes of deposition. All these circumstances give to the primary argillaceous rocks a determinate aspect. The limited limestones which interlaminate the mass are seldom so crystalline as those in gneiss and mica-schist, and they, as well as the upper and some other parts of the slaty rocks, generally yield organic remains, occasionally in great abundance. These are almost wholly marine (local deposits of land-plants occur), and the animals belong to invertebrate tribes—*Zoophyta*, *Conchifera*, *Crustacea*—and augment in number and variety as we pass from the lower to the upper parts of this series of rocks. [ORGANIC REMAINS.]

From a contemplation of the slaty rocks it results:—

1. They not unfrequently rest on the granitic rocks with scarcely any interposition of gneiss or mica-schist (Cornwall, Cumberland, &c.)

2. The proofs which they offer of the existence of dry land are chiefly (or wholly) derived from the organic remains of plants, which are not certainly known among the lower groups, but become tolerably plentiful in the upper parts of the systems.

3. The marine organic remains, shells, corals, *Crustacea*, &c., are very scanty in the older systems, and grow more and more numerous and varied towards the upper strata.

4. The forms and structure of these earliest known fossil races of animals have no extraordinary degree of simplicity, nor are they confined to the lowest or least complicated tribes of *Invertebrata*.

5. The alterations which the rocks have undergone by the action of heat are general, sufficient in most countries to superinduce new structures (slaty cleavage), but not to destroy the traces of organic remains.

A greater resemblance appears among these fine-grained strata to the deposits from modern waters than is found in the earlier rocks: there is less of peculiarity in their laminar and stratified structure; they are more varied; and the alternations of deposits indicate greater variety of natural processes and new conditions, such as the elevation of land, the wasting effects of the atmosphere, and littoral agitation, might occasion.

We may suppose, in order to account for the origin and gradual augmentation of the traces of organic life, that the flow of heat from within the globe to the surface was retarded by the effect of previous cooling, and by the addition of the older sedimentary rocks above the granite; and this is in harmony with the fact that generally the limestones of this system are less crystallised than those which are of older date. [CAMBRIAN ROCKS; CUMBRIAN ROCKS; SILURIAN SYSTEM.]

Passage from the Primary to the Secondary Period of Geological Time.—Before the close of the Primary period we find that some limited tracts of land were reared above the waters, so as to nourish the plants which occur in the grauwacke slates of North Devon and the banks of the Rhine (supposing, with the general opinion, that the fossiliferous rocks of Baden, &c., are of this age). The sea had become entirely fit for the residence of marine *Zoophyta*, which abounded so as to constitute reefs and islands; *Conchifera* and *Gasteropoda* forming extensive beds; *Trilobites* of many kinds, and a few traces of fishes. These however are chiefly in the uppermost of the primary series, and would be ranked as transition deposits by all geologists who use that now neglected and somewhat hypothetical term. Yet it is impossible not to be struck by the gradation of character which connects into one long series the granitoid gneiss and the arenaceous Ludlow rocks; the fine-grained gneiss and mica-schist with the fissile Snowdon slates and argillaceous Wenlock shale. In proportion as the deposits on a great scale resemble in character of accumulation those of modern times, so the organic remains appear more and more abundant. Some general change of physical condition, such as perhaps only a change of heat will explain, must evidently be admitted as an hypothesis to connect together this series of phenomena.

After the deposition of the primary strata, the interior forces of heat, no longer operating by a gradual metamorphosis of the previously deposited strata, and by a regulated change of the condition of the sea, appear to have been thrown into a state of critical action, and to have operated on the aqueous deposits of ancient date, as at this day the volcanic fires below affect the sedimentary strata accumulated from water above. There is hardly a mountain-range of much importance throughout the world where the effects of great convulsive movements affecting the primary strata cannot be seen: frequently it is ascertained to be the case that these movements happened before the production of any of the secondary rocks; and upon the whole it is evident that the crust of the globe was broken up and disturbed, and the relative geographical distribution of sea and land materially changed by the disturbance. The effects immediately appear: the introduction of a new order of sedimentary deposits, with new geographical relations; the extinction of old and the creation of new groups of organic beings; the commencement of a new act (so to speak) in the great history of the earth.

What relation do the great convulsions here alluded to bear to the movements of a modern earthquake? They are unquestionably due to the same general force, namely, internal heat: a disturbance of the equilibrium of this force is in each case to be admitted—the causes and effects are analogous—but is the modern earthquake due to a physical agency of equal intensity with that which occasioned the ancient convulsions of the earth's crust? The uplifting of a mighty range of mountains is a common event, a characteristic occurrence of early geological periods: minute and partial changes of level accompany some modern earthquakes. There is no possibility of explaining the former by the latter, except by taking them as differential quantities, proportioned to the time elapsed, assuming that they always (or on an average) operated in a certain direction; and thus summing an almost infinite series of minute changes to make one decided revolution. This is, and must necessarily be, the view of the advocates of the invariable constancy of the measure of natural agencies.

It is enough, in reply to this speculation, to point to the phenomena which require explanation: they are too mighty in extent, and have too much simplicity and even rarity of character to allow of the faintest belief that this hypothesis can be true. On a minuter inspection this conviction is deepened by the want of any proof of the occurrence of these thousands of small movements, which must have succeeded one another for the production of the given effect. On the contrary, the enormous and simple displacements, 100 to 4000 feet in a vertical line, and ranging 10 or 100 miles in length; the mutual connection of such faults; the laws of their relative direction, and other phenomena, utterly reject such an imaginary representation of the measure of primeval igneous agency. A much less improbable view, that the whole movement of a great mountain-chain was accomplished by gradual elevation or depression, operating through long time in one direction, is apparently difficult to reconcile with the narrow and steep ridges produced, the numerous and powerful flexures of thick rocks, the sudden and great fractures, and other characteristic phenomena.

We are therefore driven to believe that the igneous effects of earlier date were far more powerfully and generally excited, at particular epochs, than is now observed to be the case. We may be satisfied that the present aspect of the earth is to be viewed as a period of comparative repose; a period of ordinary and regular action, and frequent compensation among the agencies of nature; and may satisfactorily compare it with the whole or some part of the primary period, but not use it as a measure of the violence which accompanied the transition from one early period to another, and thus, amidst great local or general disorder, restored the equilibrium of the interior and exterior agencies of natural changes. This being supposed, the volcanic excitements of modern date being taken as the terms of a series of effects of partial and local disturbances, and re-establishments of equilibrium, there may yet remain residuary phenomena not so compensated, till some critical combination of events opens a wide access to the interior energies of heat. It is even probable that such do remain. The cavities left by the ejection of lava under the Andes are probably not all compensated by the sinking of the earth in the vicinity, because of the resistance of the coherent crust of rocks above; yet such resistance is limited, and it is at least conceivable that some part of that mighty range may fall in, as did a great portion of Papaudayang in Java (1772).

What is here concluded to be true at this day for volcanic regions taken singly, may easily be assumed to be probable for large portions of the earth, when the igneous energy was capable of more general results, because not determined to many local centres of continual or intermitting effect. But we must not leave out of consideration the gradually diminishing force of heat in the globe, whether this be due to a gradual lowering of its proper temperature, or a gradual stifling of calorific chemical processes. The loss of that heat by mere radiation into the cold planetary spaces is a residual phenomenon of infinitesimal value indeed, but of general application to the whole globe, and capable in long time, and independently of local volcanic action, of amounting to a tremendous force. For the heat of the surface of the earth being determined by the heat of the sun and the cold of its planetary path, the exterior crust would contract less than the interior nucleus, and it would depend on various considerations whether at all, and after what intervals, a violent crushing of the crust should happen to relieve the extension of the solid or fluid nucleus. During the earlier periods of refrigeration such critical disruptions may have heen frequent; at later times they would occur after long intervals, with greater violence; and finally, when solidification had gone to a certain depth, there might be no subsequent paroxysm, so long as no external agency came to aid the interior tension.

It may perhaps be worth remarking that the atmosphere of the earlier eras of the world known to geology must be supposed to have transmitted light, much as happens at present, else we should not find the eyes of fossil trilohites constructed as are those of analogous *Crustacea* at this day. (Buckland, 'Bridgewater Treatise.')

Secondary Periods of Geology.—On the undulated hed of the sea, round the ranges of primary rocks raised in insulated tracts by great convulsion, secondary strata were formed, sometimes evidently derived from the waste of the primary strata, through the influence of atmospheric agency, or the wearing of the sea on its shores. But a considerable portion of these strata is of purely marine origin; the calcareous strata may be considered as derived from chemical decomposition of the sea-water, separated from it by the vital functions of *Mollusca* and *Zoophyta*, or generated hy springs rising in the sea and loaded with carbonate of lime. Of all these modes of formation modern nature offers illustrations, some of them so extensive as to admit of comparison with many of the ancient limestone rocks. Others of the secondary rocks appear to have heen formed of ejected volcanic matter, ashes and scoriæ, which by diffusion in water have settled into deposits of considerable extent. The total thickness of the secondary rocks is but small when compared with that of the primary groups, nor are they, it is probable, spread over such exteusive areas; hut in the variety and number of alternations of the different sorts of rocks and in the diversity of their imbedded organic fossils they are altogether superior. There is among them far more of the differences which separate oceanic from littoral deposits; and we see ahundant proof that during their aggregation the arrangements of nature were extremely analogous in general features to what we now see, however great and numerous the points of difference may be.

On an attentive consideration of the several systems into which the secondary strata are grouped, namely (in the order of superposition),—

Cretaceous System;
Oolitic System;
Saliferous, or New Red-Sandstone System; and
Carboniferous System,

it will be perceived that to each of them belong littoral, marine, and oceanic deposits; sandstones having heen chiefly collected amid the agitation of the shores, clays accumulated in quiet hays or gulfs, and limestones aggregated in deeper water; and in each system, each of these classes of deposited rocks contains somewhat characteristic, if not entirely peculiar: sandstones, more or less felspathic, dark hituminous shales, and gray limestones occur in the carhoniferous system —red or blue colours belong to the sandstones and clays, and magnesiau combinations to the limestones of the next incumbent rocks; light-coloured sands and pale-hlue clays, with yellowish limestones, mark the oolitic system; and green or ferruginous sands, marly clays, and soft white limestones distinguish the cretaceous rocks.

These distinctions are important, as guiding us to a right general view of the changes of physical conditions which occasioued them. These it is prohable related chiefly to hydrography, and when we have geological maps complete enough to make the required comparisons as to the extent and distrihution of the rocks, it appears possihle that the direction of oceanic currents, the lines of ancient houndary of land and sea, may become sufficiently known to determine the particular suhterranean movements which introduced new conditions aud produced new deposits in a given basin of the secondary ocean.

Each of the great systems alluded to is characterised hy the plants and animal remains which lie in it: the *Lepidodendra* of the carhoniferous sandstones and shales yield place to the *Voltziæ* of the red-sandstone, and the *Cycadaceæ* of the oolites; the *Productæ* of the carboniferous limestone are never seen among the oolites, which abound with *Trigoniæ*, *Pholadomyæ*, &c., nor in the chalk, from which these forms are absent; ammonites belong to all the systems, but the groups differ in each; belemnites are confined to the two upper; hamites, scaphites, &c., are scarcely met with out of the cretaceous rocks.

These statements might be enormously multiplied [ORGANIC REMAINS], but enough is said to show that the great features of lithological distinction are accompanied hy striking characters of organic remains. These characters, so far as marine life is concerned, may evidently be understood by the same inference of a change of oceanic currents; but the differences of the vegetable world seem to bespeak a general change of the characters of climate.

Reviewing the four systems in succession, we shall find circumstances in each strongly indicative of peculiar combinations of the physical agencies of nature.

Carboniferous System.—To what shall we ascribe the abundance of vegetation which furnished the materials of our coal strata?—an ahundance so great as, upon any hypothesis of accumulation on the spot where the plants died, or in the sea to which currents drifted them, appears to have no parallel, unless amongst the most umbrageous forests of Tropical America. By the gradual decay and periodical transport of the woods on the Mississippi or Orinoco we may perhaps best understand the accumulation of many heds of coal, alternating with a far greater numher of much thicker earthy sediments; hut even these aboriginal forests seem unequal to produce such enormous coal deposits as we find in Britain and other parts of the northern zones of the globe. The circumstances, whatever they were, which favoured this development of vegetable power, were never repeated, at least in these zones, though deposits of a similar nature to the series of coal strata, and likewise containing fossil plants aud thin beds of coal, diversify the sand and sandstones of the oolitic, cretaceous, and tertiary eras.

As a general inference we may observe that all the great thickness (2000 or more yards) of the carhoniferous system (excepting perhaps part of the old red-sandstone series) is clearly derived from wasted lands or sea-coasts, or from a decompositiou of the sea-water by vital or chemical agency. [COAL; COAL FORMATION.]

Whatever was the length of time which elapsed during the accumulation of the carhoniferous strata, it appears to have passed with little disturbance of the level of land and sea; for not a single example (we believe) is mentioned of any real unconformity of stratification in the whole series, from the base of the old red-sandstone to the uppermost line of the coal strata. The ordinary agencies of the atmosphere and the waves were in full employ, and some traces of volcanic eruptions appear in the trap of Derbyshire aud the north of England; hut there is not in the accumulation of the often repeated alternations of limestone, sandstone, shale, &c., of the carboniferous system, anything to require the supposition of greater general convulsions. It was a period not of repose, but of regular and orderly action among the agencies of nature, so far as the parts where now Europe and North America are situated: and the mineral deposits and organic remains are to he compared with existing operations of nature, in order to learn the physical coudition of the ancient land and sea.

After the formatiou of the carboniferous strata was ended in Europe and America, the long tranquillity of the ocean in these parts was broken by extensive and violent concussion, so that hardly a single square mile of country can anywhere be found which is not full of fractured and contorted strata, in consequence of subterranean movements which mostly preceded the accumulation of the next system of strata.

The relations of land and sea were so greatly changed hy these transient convulsions, that the new ridges of land and islands appear to have been variously scattered in the ocean which flowed round the already uplifted Grampian, Scandinavian, and Welsh mountains. An equal or greater extent of laud appears to have heen elevated in Ireland, but with less violence and concussion; and it is remarkable that some of the greatest faults produced at this epoch were almost wholly unaccompanied hy the irruption of any igueous rocks, or any other signs of merely volcanic action (Craven fault, great dyke of Tynedale, South Wales coal-field, &c.)

The Red-Sandstone System, which is deposited upou aud arouud the broken tracts of the carhoniferous system, presents us in some respects with new conclusions, which however seem almost equally to apply to the old red formatiou. No douht the sands and clays of this system were collected from wasted land aud sea-coasts, and deposited in shallow waters. But whence came the red aud greenish colours so characteristic of these strata and the analogous old red formation? The grains of sand which compose much of the rocks are not red, hut white rolled quartz sand, surrounded hy red peroxide of iron like a varnish. From none of the older rocks could this ahundant red pigment be derived so as to stain the whole sea-hed for 1000 feet or yards in depth. It has been thought that volcanic action alone can explain the occurrence of this iron. It is not however improhahle that the oceans which deposited the red-sandstone may have held protoxide of iron dissolved in carhonic acid; aud that from this solution the peroxide of iron was precipitated, as is seen in iron-springs at the present day.

Instead of the great quantity of vegetable matter huried in the coal tracts, we have in the principal part of the red-sandstones hardly a few insignificant traces—so few in England that scattered fragments are valued in geological reasoning; neither are the marine reliquiæ of the magnesian limestones in the midst of the red rocks at all plentiful, except in a few spots. Even taking the richer German series as a type, the red-sandstone rocks must he pronounced singularly deficient in organic fossils; and as, generally speaking, the same deficiency of organic life helongs to the older red-sandstone below the mountain limestone, it is at least a plausihle suppositiou that the causes of the red colour and paucity of animal life are somehow closely connected. If we imagine that by reason of the great convulsions which followed the carboniferous era new currents were hrought into the same areas of the ocean from tracts yielding ahundance of new sediments, the extinction of organic life would he the natural consequence, to he followed afterwards by a gradual revival—which is nearly the truth. In the magnesian limestones of this system expire many of the forms of the older carboniferous period, and at higher levels (as in the Muschelkalk) we find a strong resemhlance of the marine *Zoophyta* shells and *Crustacea* to those of the younger oolitic system. Upon the whole there seems reason to think the new red-sandstone system could not have occupied a long time in its formation compared to other deposits of equal thickness. [RED-SANDSTONE FORMATION.]

Oolitic System.—Into the same European and Asiatic basins which received the red clays, red sands, and magnesian limestones of the last system, subsequent agencies brought blue clays, sands more or less ochraceous, and limestones characterised by an oolitic texture. These deposits are parallel to the old rocks below, and no trace of any change of level in the region where they occur has been noticed in England—perhaps not in Germany. Must we refer to some distant convulsion for an explanation of the change of sediments, and for the equally great change, or rather sudden development, of organic life, which comes in with the oolitic era? New and more abundant forms of plants (*Cycadeæ*), with many varieties of *Zoophyta*, *Mollusca*, *Crustacea*, fishes, and gigantic reptiles of the land, rivers, and the sea, mark the oolitic rocks, and render them justly comparable, as a system, to the great carboniferous assemblage of strata. Locally indeed the oolitic rocks yield coal among the interpolated grits and shales, just as happens among the rocks interstratified with the older mountain limestone.

The resemblance of the oolitic to the carboniferous limestone tracts is extremely great in general features; and the reason is that both are essentially sea-deposits, characterised by calcareous rocks formed in the deep sea, and liable to admixtures of sandstone and shales along the shores. In such situations each is carboniferous. Both are highly rich in oceanic life, but during the formation of the oolitic rocks there is no proof that anywhere such excessive richness of vegetation was renewed on the land as that which yielded the mass of coal-plants in an earlier period. [OOLITIC SYSTEM.]

Cretaceous System.—The last portion of the series of secondary strata was deposited in the same oceanic basins as the earliest as far as Europe is concerned, but this is not the case in America. Generally in Europe the cretaceous rocks have their stratification parallel to that of the oolites, though some uncomformity in this respect occurs in Yorkshire and Dorsetshire; and in the south-east of France dislocations affected the oolitic strata before the production of the cretaceous rocks. But these comparatively slight movements of the bed of the sea appear totally insufficient to account for the complete change in the chemical and mineralogical character of the rocks, and the new orders of *Zoophyta* and *Mollusca* which date from the commencement of the cretaceous era.

Sands coloured green by silicate of iron, white soft limestones with beds or nodules of flint, seem to bespeak an origin from the waste of other lands than those which discharged other sands into the ooliti-ferous sea, and other modes of chemical or vital action in the sea; yet a scrupulous analysis of the oolitic system shows in its upper part analogies to the cretaceous rocks so strong and so various as to render it probable, if not certain, that the new conditions characteristic of the new system were gradually or partially introduced till they entirely predominated—for greensands alternate with the uppermost of the oolitic limestones in the Alps, flinty nodules lie in the calcareous grit and Portland oolite, and chalky limestones constitute the great portion of the latter rocks in some situations of England. It is to be regretted that we are so little able to determine upon good evidence what the new conditions influential on the deposits of the cretaceous rocks were; for their effects are very similar along a great range of the Atlantic coast of North America from New Jersey to the Mississippi, and throughout the interior of Europe.

The cretaceous period was not ended in England by dislocations situated in or even near that part of the surface. In Ireland eruptions of basalt of enormous extent cover the chalk, and indicate a crisis of volcanic disturbance. In France, Elie de Beaumont refers to the concluding part of the cretaceous period dislocations which range north-north-west in the Jura, and traverse the primary mass of Mont Viso. After the chalk formation was completed in the south of France the Pyrenees were uplifted to a great height, so as to limit the tertiary basins of the south of France; and it is supposed that at the same time the Apennines and the Carpathians experienced an upward movement. Conjecture has even joined to these the Alleghanies; but it may be gathered from Professor Rogers's reports on the geology of America ('British Association Reports'), and accordant notices of Featherstonhaugh and other competent geologists, that an earlier date should be allowed to that mountain range. [CHALK FORMATION.]

Tertiary Periods.—In general no contrast can be more complete than that between the secondary and the tertiary stratified rocks: the former retaining so much uniformity of character, even for enormous distances, as to appear like the effect of one determined sequence of general physical agencies; the latter exhibiting an almost boundless local variety, and relations to the present configuration of land and sea not to be mistaken. The organic bodies of the secondary strata are obviously and completely distinct from those of the modern land and sea; but in the tertiary deposits it is the resemblance between fossil and recent kinds of shells, corals, plants, &c., which first arrests the judgment. In general there is a decided break between the two groups of rocks—a discontinuity which is nowhere completely filled. Yet, besides the pseudo-tertiary or transition chalky rocks of Maestricht and the Pyrenees, and the conchiferous marls of Gosau, we have in England and France above the chalk a prevalence of green and ferruginous sands extremely similar to those below. Perhaps they have been derived from the waste of these older rocks: Sir Charles Lyell supposes the tertiaries of the London basin to have been formed from the waste of the secondary strata of Kent, Surrey, Sussex, and Hampshire.

With the tertiary system came into existence (if we may trust the negative evidence which the earlier strata present) many races of quadrupeds, some birds, reptiles, and fishes, extremely analogous, though for the most part specifically distinct from the modern denizens of land and water; thousands of corals, shells, *Crustacea*, &c., which present with living races quite as great analogy as obtains between the tribes of the Atlantic and the Pacific oceans of our day; the general features of land and sea as they now exist begin to appear, and there can be no doubt that in a philosophical study of the revolutions of the globe the tertiary era of geology cannot be properly separated from the existing system of nature.

Yet during the deposition of these rocks the relations of land and sea were greatly altered in Europe by the rising of the Pyrenees beyond the height they reached after the cretaceous era, and by the uplifting of the Alps from the Mediterranean towards Mont Blanc. In England we may believe the upward movement of the southern counties, connected with the Hampshire axis of elevation and the Isle of Wight convulsion, was ended before the close of the tertiary period. The eastern range of the Alps from Mont Blanc to Vienna is of later date, and may be viewed as the most marked phenomenon of elevation which accompanied or preceded the dispersion of erratic rocks in Europe. [TERTIARY SYSTEM.]

The following table, from Professor Ansted's 'Elementary Geology,' gives a summary view of the various strata of the earth, arranged according to the latest authorities, and also gives the foreign equivalents of the various British rocks:—

Table of Classification of Rocks.

TERTIARY EPOCH.

British.	Foreign Equivalents or Synonyms, and chief Foreign Localities.
Modern Deposits:—	
Raised beaches Peat bogs Submerged forests Deposits in caverns Shell marls	Similar appearances in Northern Europe, Siberia, and America.
Newer Tertiary, or Pliocene Series:—	
1. Upper gravel and sand 2. Till 3. Mammaliferous crag 4. Fresh water sand and gravel	These beds or their equivalents are known in various parts of Northern Europe or America. Other but very different deposits are the newer beds of Sicily. Others again are found occupying a large part of South America.
5. Red crag	Subappenine beds. Brown coal (of Germany). Belgian tertiaries (crag). The Sivalik beds (India) are supposed to belong partly to this period.
Middle Tertiary, or Miocene Series:—	
6. Coralline crag	Touraine and Bordeaux beds. Part of the Molasse of Switzerland. Vienna basin. Certain European, Asiatic, North African, and North American beds.
Lower Tertiary, or Eocene Series:—	
7. Fluvio-marine beds 8. Barton clays 9. Bagshot and Bracklesham sands 10. London clay and Bognor beds 11. Plaster and mottled clays, sands, and shingles	Paris Basin. Central France. Molasse of Switzerland (lower beds). Belgian tertiaries. Various beds in Western Asia and India. Various beds in North and South America. Nummulitic beds.

SECONDARY EPOCH.

British.	Foreign Equivalents or Synonyms, and chief Foreign Localities.
Cretaceous System:—	
12. Upper chalk with flints 13. Chalk without flints 14. Lower chalk and chalk marl 15. Upper greensand 16. Gault Lower. 17. Lower greensand Lower. a. Kentish rag Lower. b. Atherfield clay Lower. Speeton clay	Scaglia limestones of the Mediterranean. Maestricht beds. Senonian division of D'Orbigny (Craie blanche). Turonian beds of D'Orbigny, (Craie tufau); Quadersandstein of Germany. Albian beds of D'Orbigny. Plänerkalk of Germany. Neocomian of Switzerland and France. Hilsthon of Germany. Pondicherry beds. Bogota beds, South America. (?) Aptian beds of D'Orbigny. (?) Hils-conglomerat of Germany.

Wealden System :—	
18. Weald clay	Near Boulogne.
19. Hastings sand	North of Germany.
20. Purbeck beds	
Oolitic System :—	
Upper. 21. Portland stone	Jura limestone is the usual continental synonym of our oolitic series.
a. Limestones with clay and cherty hands	Lithographic limestone of Blangy.
b. Siliceous sand	Honflenr clays.
22. Kimmeridge beds	Solnhofen beds. Beds in South of Russia and in India.
Middle. 23. Coral rag and calcareous grits	Nerinean limestone.
24. Oxford clay	Argile de Dives.
a. Stiff clay	
b. Kelloway's rock	
Lower. 25. Cornbrash	Étage Bathonien is the name given by D'Orbigny to our lower oolites.
26. Forest marble	Calcaire à polypiers.
27. Bradford clay	Calcaire de Caen.
28. Great oolite	
29. Stonesfield slate	
30. Fullers' earth	
31. Inferior oolite	
Liassic System :—	
32. Alum shale	Calcaire à gryphites.
33. Marlstone	
34. Lower lias	
35. White lias	
Upper New Red-Sandstone, or Triassic System :—	
36. Bone-bed of Aust Cliff	Keuper marls, or Marnes irisées.
37. Variegated marls, with salt and gypsum	Muschelkalk.
38. Variegated sandstones	Bunter sandstein, or Grès bigarré.

PALÆOZOIC EPOCH.

Magnesian Limestone, or Permian System :—	
39. Magnesian limestone	Zechstein.
40. Dolomitic conglomerate	Kupfer Schiefer and other shales.
41. Lower new red-sandstone	Rothe-todte-liegende.
Carboniferous System :—	
42. Coal measures	The coal-measures occupy an important place in various parts of the continent, in Belgium, France, the Rhine, South Russia, and also in North America; in various parts of Asia, and in Australia. The foreign synonyms are, Steinkohlengebirge, terrain houillier, terrain carbonifère, and terrain anthraxifère.
a. Gritstones	
b. True coal-measures	
c. Fresh-water limestone of Burdie House, near Edinburgh	
43. Millstone grit	The millstone grit is generally a bed of subordinate importance out of the British Islands.
a. Coarse gritstones	The Kiesel Schiefer of Germany is an equivalent of the carboniferous limestone.
b. Laminated shales	The Belgium limestone beds and others in Northern Bavaria are in the same part of the series.
44. Carboniferous limestone	
a. Bands of fossiliferous limestone	
b. Shales (calp, culm)	
Devonian, or Old Red-Sandstone System :—	
45. Quartzose conglomerates (old red-sandstone) in South Wales and Scotland; represented by coarse red flagstones and slates in Devonshire and Cornwall	Devonian beds are well known in Belgium, the Eifel, Westphalia, and North Bavaria. In Russia the old red-sandstone appears, and contains similar fossils to those found both in the corresponding beds in the British Islands, and also in Devonshire and Herefordshire. The paleozoic beds of Australia are supposed to be contemporaneous.
46. Cornstone and marl of the old red-sandstone. Calcareous slate, limestone, sandy beds, and conglomerates of Devonshire and Cornwall.	
Upper Silurian Series :—	Silurian strata extend over much of the northernmost parts of Europe, and corresponding latitudes in America. They have been found in Brittany, in Westphalia, near Constantinople, and in Asia Minor. In South Africa, the southernmost parts of South America, Australia, and China, different contemporaneous rocks have been determined. In mineral character they are generally distinct from the English beds, but offer no marked characters uniformly present.
47. Tilestone	
48. Ludlow group	
a. Upper Ludlow shales	
b. Aymestry limestone	
c. Lower Ludlow shales	
49. Wenlock group	
a. Wenlock limestone	
b. Wenlock limestone	
Lower Silurian series :—	
50. Caradoc sandstone	
51. Llandeilo flags	

We may now turn to the consideration of the present aspect of the globe.

According to every view of geological causes and effects, the present aspect of our planet is the result of all its previous changes; these changes cannot be completely understood if we leave out of consideration the daily variations which occur in the condition of the earth, nor can the operation of existing agencies be completely represented to our minds without calling in aid the inferences derived from a study of earlier phenomena.

One of the most important things ascertained by geological investigation is the certainty that the operations by which stratified rocks were formed in the sea-bed, and the igneous rocks uplifted from below, were repeated nearly in the same succession over most parts of the globe. Some of the formations are very extensive: in all countries the lower strata are of the character of gneiss, mica-schist, slate-rocks, &c. These primary strata may almost be termed universal: the organic forms which they contain, though few, are very similar, or exactly identical, over enormous areas; and there can be no doubt that during the deposition of these ancient rocks the earth enjoyed an uniformity of conditions over its surface never since repeated. There is no proof that land existed anywhere in the earlier part of this period—no probability that any part of our continents or islands then stood above the water. At the close of the primary period the effect of elevatory forces was manifested by the existence of some narrow ridges and peaks of rocks, corresponding to some of our present mountain tracts, as the Grampian and Cumbrian mountains, and of others now vanished, which nourished the forests and herbs whose destruction has yielded coal.

Through the secondary period this elevation of land proceeded gradually, or by intermitting action, till at the close of that period some of the principal features of European geography were visible; the ocean was contracted and divided into many basins and gulfs, some of which remain, as the Adriatic, English Channel, German Sea, &c.; while others, as the Vale of the Danube, Sea of the Rhine, &c., have been dried by further elevation.

The same elevatory action continued through the tertiary eras completed the geographical features of Europe, and though we cannot trace so minutely in other parts of the world the contemporaneous changes, enough is known to assure us that the same causes have, within the same general limits of time, produced, in all quarters where dry land appears, the same phenomena.

In the preceding pages we have spoken of the elevation of land from the sea as a thing perfectly well understood, and admitted as a basis of reasoning. It is so admitted by geologists of every shade of opinion who wish to explain effects by real causes. We shall here present a short sketch of the reasons which have produced on this important point so general an agreement among geologists.

1. In existing nature the combined influence of the exterior and interior causes of change cannot materially affect the level of the sea (as estimated by the mean radius of its surface). Within sensible limits the sea-level is now permanent. 2. The land now above the waters was formerly below them, and could only have been laid bare by the elevation of parts of the sea-bed, or by the abstraction of the ocean to other regions, either through depression of its bed or through a displacement of the axis of rotation, or by an universal diminution of the quantity of water on the globe, or by a change of the oceanic level through great alterations of temperature at the surface or through the mass of the globe.

In examining these possible modes of desiccation of land, geology must have recourse to collateral science. The two last hypotheses, namely, of a change of oceanic level, without change of external form or axis of rotation, are insufficient for the purpose. Sound reasoning rejects the supposition of an indefinite waste of oceanic waters for miles in depth, because the position of our planet in space yields no escape for the water; nor is there any ground for believing that the quantity fixed in mineral compounds since the date of the earliest strata is of much importance. A general change of temperature of the globe would certainly alter the relative level of land and water, because their rates of expansion and contraction are unequal. Between the boiling heat, 212°, and what is probably below the mean temperature of the actual seas, 40°, the contraction of the water would be about ·042 of the whole quantity. The land certainly would contract less, and thus by a general cooling of the globe the ocean-level would relatively sink. To put the case to extreme, we shall suppose the contraction of the land = 0, the area of the water to remain unchanged, and the mean depth of the sea ten miles; the reduction of level of the ocean would be $\frac{42}{100}$ of a mile = 739 yards. Now, as all the conditions of the problem have been taken in extreme, as the deepest part of the sea probably does not exceed ten miles, as one quarter of the spherical surface is land, and the area of the sea must diminish as its level sinks, it is very obvious that the greatest possible change of oceanic level from this cause could only go to one, two, or three hundred yards at most; and therefore it is impossible by such means to explain the desiccation of land from 1000 to 10,000 or 20,000 feet high.

Moreover, during this cooling of the land and sea the whole globe would contract; and from this cause the mean radius of the ocean diminish and its mean depth augment, so as to reduce still more the possible extent of land that could be drained by its change of dimensions.

The attraction of the ocean to other regions would lay dry parts of its bed; and if astronomical science permitted geologists to change at their pleasure the position of the axis of rotation of the earth, few difficulties need stop the career of speculation; but the earth is a spheroid of revolution, and if the attraction of the heavenly bodies in the various positions which it takes with regard to them does not disturb its axis of figure, neither can it be thought that the volcanic fever of its surface can so alter the interior densities as to cause any sensible change in this respect.

But that the bed of the sea may have sunk, that other continents than ours may have fallen below their ancient level, may be assumed as readily as the rising of the existing land, but with this restriction, that the sinking of the bed of the sea requires to be far greater than the rising of the land, because three-quarters of the globe are covered by water, and thus a small difficulty is overcome by introducing a greater.

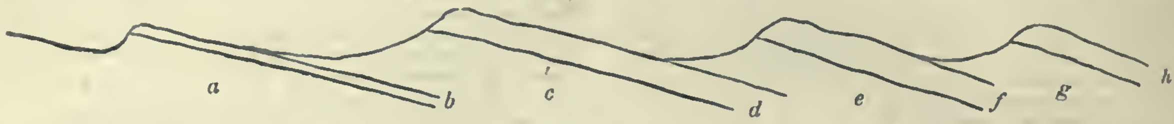

Fig. 4.—*a*, Red marl; *b*, lias limestone; *c*, lias clays; *d*, lower oolite formation; *e*, Oxford clay; *f*, middle oolite formation; *g*, Kimmeridge clay; *h*, upper oolite.

Finally, on turning to the phenomena connected with mountain chains, it is perfectly certain from the position of the strata—often vertical or contorted in the sides of chains, highly inclined near them, and gently sloping at greater distances—that these rocks have been displaced by an elevating force acting from below. The direction of the force, the geological time of its occurrence, its sudden or gradually accumulated intensity, and many other characteristic circumstances, can be determined; and upon the whole no doubt remains that elevating movements have raised the land, and there is no reason to deny that depressing movements may have sunk the bed of the sea.

Throughout all the globe the outlines of land and sea depend principally on the disposition of mountain chains and groups, which in every instance yet known are certainly shown to have been raised by mechanical agency, generally with a degree of violence so great as to require the supposition of great and general excitement of the subterranean forces of heat. America, for instance, derives its form from the chains of the Andes and Rocky Mountains, the littoral range of Brazil, the Alleghanies, &c., mountains probably of very unequal antiquity. The Ghauts define the western side of India, as the Atlas mark the north-western border of Africa; the Pyrenees and Sierras give the form of Spain; the Cornish, Welsh, Cumbrian, Lammermuir, and Grampian ranges explain the figure of England and Scotland.

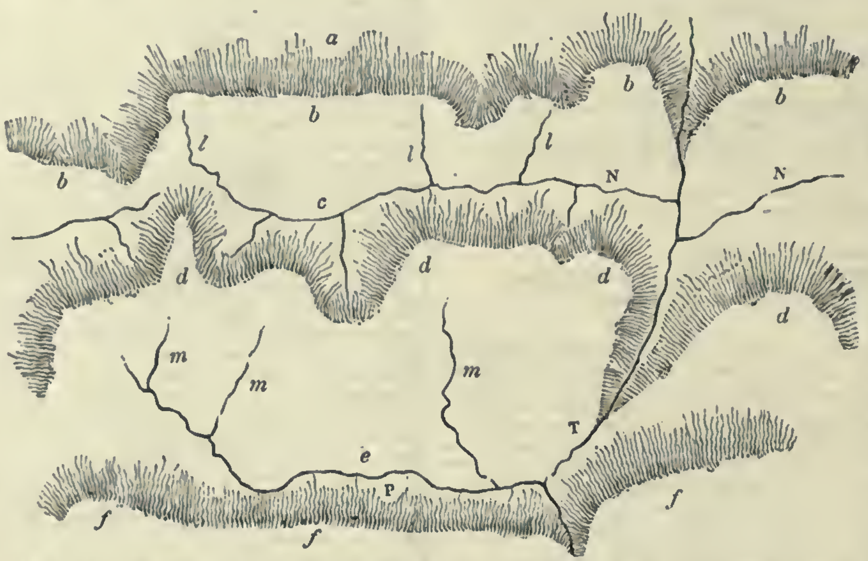

Fig. 5.—*a*, *b*, *c*, *d*, *e*, *f*, have the same meaning as in *Fig.* 4; *l l l*, *m m m* valleys which descend with the slope of the strata, here supposed to dip south; NN, and P, longitudinal valleys, or such as run parallel to the outcrop of the strata; T, a transverse valley, uniting the longitudinal ones.

Fig. 6.—The letters have the same signification as in *Figs.* 4 and 5.

Frequently however this dependence of the form of the existing land upon the ranges of mountains is disguised by the extent of comparatively plain country which separates the mountains from the sea. Thus, all the eastern half of England might seem to have its form independent of the narrow ridges of the western mountains; and it is but a vague relation which links the Baltic, the Black Sea, and the Caspian to the Harz, Saxon, Carpathian, Caucasian, and Uralian chains. In these and many other cases it is necessary to admit that the general level of the sea has subsided, or that large tracts of land have been raised gradually, or by successive movements round the mountains, which in earlier times were uplifted by more violent effects. The diagrams, *figs.* 2 and 3, illustrate the fact of the general slope of the English strata from the western mountains; but this cannot be explained by the violent elevation of these mountains, for this happened principally before the deposition of the coal strata. A large area round these mountains has since been gained from the sea by more gradual changes of level.

Similar phenomena present themselves in detached areas all over the world; but in very unequal degrees, and with unequal differences of level above the ocean, even in neighbouring tracts. It appears therefore more probable that particular regions have risen round the same points and lines which once experienced a violent upward movement. There is no reason to deny that the ocean-level may have been somewhat lowered by the subsidence of a part of its bed; but it has been already shown that no reasonable (perhaps no possible) sinking of the ocean-bed could explain the phenomena of the desiccation of even the flatter parts of the land.

The interior features of every country, in like manner, depend upon recognised geological agencies. The unequal elevation of mountain ranges above the sea is a phenomenon which will be found of great importance in geological theory. It appears to be true, at least in Europe, that the most elevated chains of mountains are those whose elevation was not ended (if, indeed, it be yet ended) until the tertiary or later epochs. Thus, the Alps, which bear on some of their heights (Diablerets) caps of tertiary strata, ascend to 15,660 feet above the sea; the Pyrenees, whose principal elevation appears to have followed soon after the chalk, to 11,270; the Carpathians, nearly of the same date, to 8675 feet: while in the Harz the older mountains (Brocken) rise to 3739 feet; in Wales (Snowdon) to 3675 feet; in the Grampians (Ben Nevis) to 4350 feet. The highest point of Norway (Schnee-Haten) is more than 8000 feet above the sea, but there can be no doubt that violent as well as gradual upward movements affected the Scandinavian ridges to a late geological era.

Raised in this manner by violent or gradual movements out of the sea, the dry land has since been subjected to waste by atmospheric action; and there is no doubt of the truth, that to different sorts of rock belong some differences of aspect, some characteristic scenery. The forms of the hills and valleys are not the same in the gneiss and mica-schist of the Grampians; the clay-slate ranges of Wales; the limestone of Derbyshire; the oolites of Gloucestershire; the chalk of Wiltshire; even single rocks and waterfalls have distinctive characters, and the whole aspect of a country changes with its geological structure. It thus appears that the nature and structure of the rocks, their elevation above the sea, and the manner in which they attained it, and the intensity and duration of the atmospheric agencies which have since affected them, are the elements which determine in every instance the physical aspect of a country.

No question in geological theory has been the subject of so much debate, with so little of correct reasoning, as that of the origin of valleys. By Dr. Hutton it was contended that atmospheric agency and running waters had excavated valleys; by De Luc the subsidence of the crust of the earth was invoked; Omalius D'Halloy introduced the consideration of dislocations on the line of the valley; and Dr. Buckland appealed to the overwhelming force of a general flood. None of these views is entirely wrong; each contains partial truth; and the complicated problem of the inequalities of the surface of the earth can be solved by combining them.

By violent elevation from the sea, rocks of whatever nature or structure, must have been variously broken and fissured. It is conceivable that some of these fissures might descend below the level of the water. During the elevation some considerable effect on the forms of the ridges and hollows would be produced by the agitated water, but the smaller modifications which they have experienced must be ascribed to atmospheric agency. In these few words we have the history of the rough hills, abrupt valleys, and deep lakes which belong to mountain chains like the Grampians, Alps, and Pyrenees.

By gradual risings or interrupted lifts of the bed of the sea, other phenomena would arise; the action of the sea upon the rocks, successively brought within the sphere of its littoral movements, would concur with the form of pre-existing land, and the entrance of its drainage waters, in extending the old and producing new valleys.

In the next diagram (*fig.* 6) the same country is represented as rising out of the sea, which penetrates by the transverse valley across the ridges of rocky hills, and flows round them up the vales of clay; its waves wasting the clays under the cliffs, and causing the top to fall, exactly on the same principle that waterfalls at this day, by wasting the argillaceous basis, break down the crowning limestone beds throughout all the north of England.

The Giesbach, on the lake of Brienz, compared with the Staubbach; Hardrow Force in Yorkshire, or Ashgill Force in Cumberland, contrasted with the Fall of Lodore, near Keswick, are in this respect very instructive; nor should the cases be neglected where, as on the coast near Scarborough, Robinhood's Bay, and Whitby, the sea now flows among the lias and oolitic rocks, and wastes their argillaceous parts on a small scale, almost exactly as in the above explanation it is supposed to have wasted the similar but thicker clays, when the whole system was rising above the waves. Pleasing illustrations of this kind of action occur in the Medlock at Manchester, the Greta near Ingleton, the sea-coast near Heysham, Sunderland, Berwick, &c. In the Isle of Wight the fresh-water limestones and clays, and the various beds of the plastic clay series about Culver, offer abundance of curious examples.

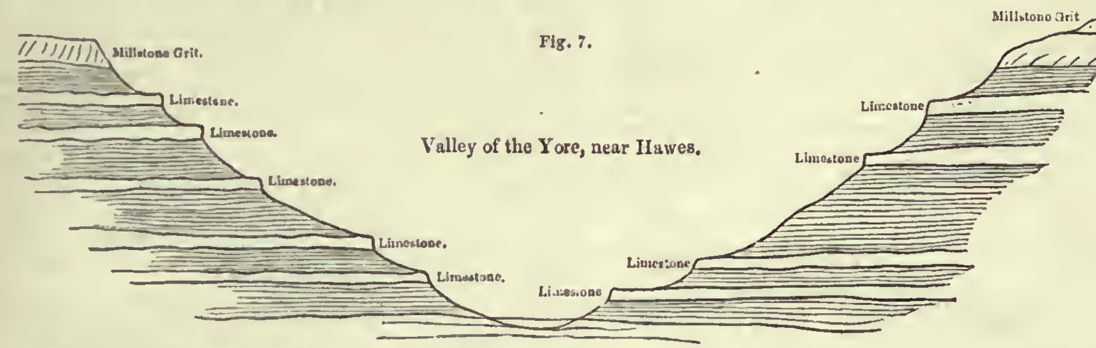
The same mode of action is traced in the forms of mountains and hills which are composed of strata of unequal resisting power; as mountain limestone and shale in the Yorkshire dales, oolite and clay in the Gloucestershire Hills, Normandy, or the Jura mountains.

The diagram (*fig.* 7), given below, represents a cross-section of Wensley Dale, which for a great part of its length exhibits, wherever a considerable rock of limestone comes to the surface, a decided projection and terrace on the hill side, and below every such rock a slope formed in the alternating shales and thin sandstones.

How much of this appearance is due to atmospheric action and rain since the river Yore has been running in its present bed, and how much to the influence of water bathing the hill-breasts at higher levels, is not easy to determine; but the correspodence of the strata on the opposite sides is such as to leave no doubt that all the vast space of the valley has been really excavated out of continuous strata; and the survey of the whole line of this and other rivers appears to refute the opinion that the existing drainage waters have carried off much of the detritus.

To conclude this brief notice of the origin of the principal inequalities on the earth's surface, it may be proper to remark that the view here given of the excavation of valleys at the time of the rising of rocks from the sea, explains the otherwise unintelligible phenomenon of dry valleys in chalk, oolite, and other calcareous strata, which

Fig. 7.



Valley of the Yore, near Hawes.

The greater number of these extended or new valleys would be directed at right angles to the axis of elevation in progress, and therefore, on the dry land, the greater number of valleys originating in these circumstances will be found to run with the dip of the strata. How exactly this agrees with the general character of the drainage channels of the secondary strata of England above the red-sandstone requires only to be mentioned; and it has been already shown that in all the south-eastern parts of England where these strata occur there is sufficient evidence that the elevation of these rocks was due to gradual and long-continued, not violent and transitory movements. While such gradual movements occurred, and strata of unequal hardness and different structure (as limestone and clay, or sandstone, in diagram, *fig.* 4), were brought within the range of littoral action, these would be unequally affected by the tidal and other currents; the softer parts would be worn away, the harder remain; and thus the red marl would be wasted parallel to the coast-line, or to a certain depth in the water, below the cap of lias limestone; the lias clays would yield beneath the crown of lower oolite; the Oxford clay be excavated below the middle oolite; and the Kimmeridge clay form a vale between the middle and upper oolites.

The exact conformity of this with the appearance in nature is well known. The general character of the actual drainage, as Dr. Smith has often and elegantly explained, may be represented in diagram, *fig.* 5, where *l l l* and *m m m* are valleys descending on the slopes of the strata, N N and P, valleys formed in softer strata parallel to the coast; T a transverse valley uniting the others.

wind and unite like the branches of a river, and have slopes and features such as to prove their origin from moving water, but contain no trace of a stream, no mark of a spring, and often no alluvial sediment.

It appears also necessary to remark that, independent of the facts here stated, there must be some importance attached to the effects likely to be produced by the violent agencies, whatever they were, to which the origin of diluvial phenomena is ascribed. The essential thing however in this case being a relative change of level of land and sea, the result of the watery agitation could only be to modify in a greater or less degree the more considerable effects of previous agencies of longer duration. Gravel heaped in particular places conceals some of the earlier slopes of land, and covers with irregular hillocks an original sea-plain, but the great features of the country remain comparatively unaffected by these transient disturbances.

Life on the Globe.—Geology enables us to behold, in the present varied and complicated arrangement of land and water, the result of many and repeated actions of causes which are not yet extinct, but continually occupied in similar operations, in different situations, and under different circumstances. The land which has been raised from the sea by internal expansion seems to be slowly wasted away by the action of water, and again restored to the deep. But new land is formed by these ruins, and volcanic fires are yet competent to raise or depress the bed of the sea.

The land is not all of the same antiquity; some regions must have been covered by trees, perhaps or rather certainly traversed by quadrupeds, before the substance of others was laid on the bed of the sea. Since life was developed on the globe, if geology has rightly interpreted the monuments of nature, there has never been any considerable period during which the land or sea was wholly deprived of organic beings; but as the condition of the globe changed, the forms of life were altered, old races perished, new creations were awakened, the sum of animal and vegetable existence was continually augmented, and the variety of their forms and habits continually multiplied, as the conditions of land and sea were diversified, until man was added to the wonders of creation, and historic time began.

If then, through all past geological time, organic life has changed its aspect as physical conditions varied—if the present physical aspect of the globe is derived from previous physical revolutions, must we look on the present system of organic being, adapted to the present physical conditions, as similarly derived by corresponding revolutions from earlier systems of life, corresponding to earlier states of the land and sea?

If the physical aspect of the globe is now changing, does its organic enrichment vary likewise; or is the relation of organic life and physical condition one of coincidence merely—one of those adjustments independent in its nature, though associated in time and situation, which offer the most convincing proof of continual superintendence of the divine lawgiver of nature?

Though we cannot here enter at large on a subject which requires the details which are found under another head [ORGANIC REMAINS], there are points of too general importance, in reasoning on the present condition of the globe, to be wholly omitted:—1. The relation of form and structure between the living and extinct worlds of life; 2. The distribution of the existing forms of life, in reference to the geographical features and geological history of different parts of the globe.

The relation of living to extinct races of plants and animals is various. In number, the Recent Flora is perhaps 100 times as considerable as the Fossil Flora, and though this is in some degree owing to the circumstance that land-plants, insects, &c., must necessarily be comparatively rare in marine strata, yet the vast number of individual plants accumulated in coal tracts does not appear to justify a very high estimate of the variety of specific forms of plants in early periods. The same is true of the marine races of shells, *Crustacea*, fishes, &c.; for both the total number of species, and the relative number to a given thickness of strata, augment from the early towards the later formations, and are greatest of all in the tertiary strata, which in character of organic life most nearly resemble the modern productions of nature.

On comparing the living with the vanished tribes of plants and animals, we are struck with the fact that hardly one species of the fossil kingdom is so peculiar in its structure that nothing at all like it is now in existence. Recent analogies of extinct forms are continually and unexpectedly presented to us by the attentive voyagers who now explore the most remote and unknown regions of the land and sea, and continually revealed to us by the discoveries of comparative anatomy, which detects in common forms traces of analogies to extinct creations formerly altogether unsuspected. Thus the belemnite, the trilobite, the ichthyosaurus, are reduced to their proper station among *Mollusca*, *Crustacea*, and *Reptilia*, and the whole extinct and living world of nature becomes united into one general system.

But this indubitable affinity between the plants and animals now living and those which adorned the world in earlier ages does not require us to adopt the speculations of Linnæus, Oken, Lamarck, St. Hilaire, and the anonymous author of the 'Vestiges of the Natural History of Creation,' that specific forms of plants and animals are no further permanent than the circumstances which surround them; that as these change those vary; that the immense variety of organic structure may have been derived from a few primitive types—the living gavial from the fossil *Teleosaurus*, the living cuttle from the fossil *Belemnosepia*, the living from the fossil *Equiseta*. This doctrine, plausible as it seems, and flattering as it is to that propensity in man to derive everything from a beginning of which his own senses may give some notion, must be rejected for three reasons:—

1. In existing plants and animals the experience of mankind, for 2000 or 3000 years, has shown no essential change.

2. There is no proof, drawn from examination of fossil reliquiæ, of this assumed change from one species to another, much less from one genus to another. On the contrary, it is a very striking truth, illustrated in almost every group of fossils, that while the same species retains through many deposits of different age its essential characteristics, new ones come into view in many of these strata, not by a gradual change, but by a sudden development.

3. The destruction of old races and the introduction of new appear in many cases to have been sudden and complete, at least locally.

In considering the distribution of existing forms of life, with reference to the geographical features and geological history of different parts of the globe, we cannot avoid being struck with the fact that each species, each genus, and often each family, of plants and animals, is especially abundant in and often exclusively confined to particular parts of the land or sea, even among those animals whose powers of locomotion are the greatest. Among fishes, birds, and swift quadrupeds, this attachment to locality is scarcely less remarkable than among Plants, Zoophytes, and *Mollusca*, which have no means of diffusing their races, except what winds and currents give. It has therefore become an admitted truth in the philosophy of natural history, that there are certain regions of the land and tracts of the sea for which particular groups of plants and animals were specially created, and to which for the most part their existence is still confined.

The living species of plants and animals which most nearly resemble fossil races are variously distributed over the globe. Tree-ferns, gigantic *Equisetaceæ*, and other plants illustrative of the Flora of the carboniferous period, may be found in Brazil, the Indian Islands, and Australia; coniferous plants occur in colder latitudes, or at greater heights in the tropics, as well as in the lias; *Cycadaceæ* occur in South Africa and Australia, and tropical America, as well as in the oolites. The recent *Trigonia* and *Cerithium giganteum* are found on the Australian shore; *Pholadomya* was washed on the island of Tortuga: and *Cucullæa* belongs to the Indian Ocean. *Lingula* is found in the Moluccas; but *Terebratula* in all seas: the nearest living form to the old fossil crocodiles inhabits the Ganges; while the bony pike, whose scales resemble those of *Megalichthys*, lives in Lake Ontario.

Geological Time.—There is perhaps no more difficult problem in geology than the determination of the length of time which has elapsed during the formation of the whole or any definite part of the crust of the earth. Time, as measured by generations of men, fails to carry us back to remote geological epochs; man is but a recent visitor of the globe; compared even to the secondary strata his date is of yesterday, for all the existing forms of life cease with the lower tertiary rocks, only small proportions of them occur in the middle of that series, and traces of men have nowhere been seen in any but the most modern parts of the stratified masses of the globe. If then the history of the human race does not commence till after the deposition of at least the greater part of the tertiary strata, by what rules shall we attempt to compare the few thousand years of his existence with the earlier periods of the history of the globe?

In a vague sense, nothing appears more obvious than the conclusion universally admitted among geologists, that the earth is of vast antiquity, yet nothing more eludes the grasp of reasoning than the seemingly easy task of computing its age. The rocks are indeed full of monuments of time, "rudera longinqui seculm præterlapsi ævi," but we have not yet learned fully to decipher them.

When we behold thousands of strata piled on one another in a regular series, each distinct by some peculiarity from the others; when we find among these the original products of chemical action (as limestone), the slow sediments from gentle motion (clays), rough sand and pebbles implying greater agitation; how can we refuse to admit that long time elapsed during the often repeated change of chemical and mechanical agencies of water over the same portions of the bed of the sea?

When among these strata we observe the remains of plants and animals, various in their kinds, regular in their distribution, so as to prove that at successive times the same part of the sea nourished successive races of animals, and buried in its sediment distinct races of plants, where in modern nature is it conceivable that such repetitious of change, in all the ranks of creation, could take place except by the aid of almost immeasurable time?

Descending to minuter inquiries, we find some particular strata composed of fragments derived from a more ancient rock, which after being deposited in water, was indurated, raised to the surface, wasted by drainage, and again collected in rolled fragments on the bed of another sea. The trees which are imbedded in certain rocks (coal-measures, lias, Portland oolite, &c.), are often known by their rings of growth to be some decads of years old, and in particular cases (Dirt-bed of the Isle of Portland) it is supposed that their whole existence passed between the formation of two beds of stone.

Every country affords examples of certain fossil shells confined to even a thin layer of shale, sandstone, limestone, or ironstone, and in some instances (near Leeds and Bradford) the youngest embryo *Goniatites* and the oldest full-grown shell are found in one bed of 6 or 12 inches thickness, in that alone, and apparently in the place of their quiet existence, so as to indicate that the lifetime of that *Goniatite* (*G. Listeri*) was consumed during the accretion of one calcareous bed, which is about $\frac{1}{3000}$th part of the thickness of the coal-measures whose history it enriches.

If again, among those strata produced by watery action we find alternations of volcanic rocks, and learn that at particular epochs in the series of deposits mountains were raised from the sea, land clothed with forests was submerged, and the physical geography of particular regions entirely changed, we see clearly that such repeated revolutions of nature agree with the history of the organic creations in refuting the narrow views of those who would limit the age of the world to the short annals of mankind.

But how are we to proceed further, so as to clothe with a more philosophical character these almost poetic notions of the immensity of past geological periods? Three orders of effects are in this respect important:—

1. The deposition of stratified rocks. 2. The changes of organic life on the land and in the sea. 3. The displacements of land, and changes of physical geography.

The phenomena of stratification are at this day repeated, and on a very considerable scale, in most parts of the world. Where great rivers sweep earthy materials and vegetable reliquiæ to the sea, as in the case of the Mississippi, Amazonas, Rhine, the Po, and other rivers, littoral aggregations take place, and new land is formed; tides and currents throw up sand-banks, or disperse the finer sediment far from the shore over the quiet bed of the ocean. From the growth of new land on the Adriatic and Egyptian coasts, by the action of the Po and the Nile, some notion may be formed of the great quantity of sediment annually transported by rivers to the sea, and both reason and experience show that the materials are there accumulated in the same manner as the ancient strata were.

But are they now accumulated with the same, with greater, or less rapidity? If equal deposits are now formed in equal times, the calculation of the age of the visible crust of the earth is as easy as it would be philosophically useless; but to assume this principle is to nullify the conclusion from it. Unless it can be shown, à priori, that atmospheric influence must have been constant through all past geological time, the assumption will not be accepted. This cannot be satisfactorily shown, for the external excitants on which the atmospheric actions depend contain variable elements. No certain conclusion then can be rested on the comparison of the mere thickness of the stratified rocks, as to the lapse of time, unless there can be found an independent scale of time which may help to interpret the other.

Such a scale of time is perhaps contained in the series of organic beings imbedded in the earth. These belong to many successive systems of life, which may be compared with the existing forms of nature, and could we establish from history any rate of change in organic life, any per-centage of species destroyed, or created in a given series of years, some considerable steps might be laid for further advance. But two or three thousand years appear to have made no change on quadrupeds, birds, reptiles, fishes, shells, or conspicuous plants. As far as can be known by study of old writers on natural history, sculptured monuments, coins, and mummies, no change of external form or internal structure has been experienced since the earliest historical era; the loss of a very few species is all that can be safely admitted; and no proof is offered of a single newly-created form, though the distribution of the different groups of plants and animals has been varied by sea-currents carrying seeds and ova, and altered by man, who has learned to conquer by obeying nature.

As far therefore as the more obvious and characteristic forms of animals and plants can be admitted to yield satisfactory evidence, the period of two thousand years since the days of Aristotle would be insufficient even as a unit of measure by which to estimate the intervals of geological time which elapsed during the deposition of strata. This conclusion is strengthened by some and weakened by other considerations. It is weakened by the circumstance that the changes of organic life appear to have been sudden; it is fortified and illustrated in a powerful degree by comparing existing nature with the tertiary era, for thus the ten or more thousand shells of this day appear to be joined to an equal number of others, into one long series of definite organic forms, which, since the date of the chalk, have admitted new and lost old species continually. Whether these new species, in any particular basin of strata, were parts of one or more new creations there, or, as may perhaps be thought probable, transferred from other centres of oceanic life, is quite unimportant for the argument as to time. The effects resemble those noticed among the older strata, the causes must be assumed to be correspondingly similar, and the times must be in some degree proportionate. Uniting therefore the tertiary and modern eras into one great geological period, we may compare the unknown quantity of time which it includes with other equally unknown and older intervals in the history of the globe, corresponding to similarly complete series of organic forms. This comparison is facilitated by the remarkable fact of the almost total distinctness of the organic beings of successive geological periods. Had the shells of successive systems of strata been gradually changed by substitution, we should have been compelled to compare not systems but formations, or even individual strata; and the conclusions might have become irremediably obscure.

The systems to be compared are:—Tertiary, Cretaceous, Oolitic, Saliferous, Carboniferous, Fossiliferous, and Primary.

The following table, extracted from Professor Phillips's 'Guide to Geology,' gives the proportionate thickness and number of organic forms of these systems:—

Strata.	General thickness.	Number of species of organic remains to 100 ft. thickness.
Tertiary	2000 feet	141
Cretaceous	1100 feet	70·7
Oolitic	2500 feet	45·6
Saliferous	2000 feet	8·2
Carboniferous	10,000 feet	4·7
Primary	20,000 feet	2·0

Hence it is very obvious that any conclusions as to time, drawn from the mere number of species which were developed and destroyed with any system of strata, will be totally opposed to others based on the observed thickness of the strata. The inferences are obvious and important; the numerical relations of organic life to the amount of stratified deposits are variable; one cannot be used as a measure of the other; the variety and abundance of organic life has been augmenting from the primary to the tertiary eras, or the deposition of strata was in the early ages of the world fifty times as rapid as in the tertiary period. This latter conclusion can never be allowed, since the fossiliferous primaries show clearly their origin from land-floods and littoral currents, and these depend on influences which cannot be supposed to have varied in any such proportion.

It thus appears that neither the numbers of organic fossils nor the thicknesses of strata afford a perfectly satisfactory scale by which to measure past geological time; but whichever of them be preferred, the age of the world cannot be estimated at less than several times the whole tertiary period, and compared with this the historical portion of time, which dates from the birth of man, contracts to a point.

By uniting the two considerations above stated, it will appear certain that the rate of organic development has been augmented, and probable that the rapidity of sedimentary deposition diminished since the primary era; and it is no slight argument in favour of the hypothesis of a gradually cooling globe, that both these phenomena are natural consequences of it—for that the greater influence of the earth's proper heat in the earlier epochs would favour the mechanical but limit the vital activity of nature seems to require no proof.

If however independent proof were required of this change of ratio among the agencies of nature, we must appeal to a third order of phenomena most certainly characteristic of disturbances of the equilibrium of the earth's proper temperature: the fractures, contortions, and other marks of the violent elevation and depression of the crust of the globe.

From what has been already stated it is very clear that the principal phenomena of this description occurred specially at particular intervals during the long periods of geology; for example, after the primary period, after the carboniferous era, before and after the accumulation of the cretaceous strata, after many of the tertiaries were produced. Now, on comparing the amount of disturbance effected at these epochs respectively, we are unable to perceive that the efficient causes have diminished in force; for the elevation of the Alps in the tertiary period is apparently quite as conspicuous a phenomenon as can be found among older geological monuments. M. Elie de Beaumont, to whose speculation as to the geographical characters of subterranean movements allusion has already been made, supposes that as many as twelve distinct epochs of mountain-elevation may be recognised. The following is a brief summary of the classification which best suits the geology of England:—

Geological Period.	Effects noted.	Localities.
1. After the deposition of the Skiddaw rocks.	Beds of argillaceous conglomerates.	Derwent-Water.
2. During the deposition of the Snowdon rocks.	Porphyry, greenstone, and trappean conglomerates.	Under Helvellyn, in Snowdon, &c.
*3. After all the primary strata were deposited.	Principal elevations of primary rocks.	Grampians, Lammermuirs, mountains of Cumberland and Wales.
Conglomerate Rocks follow in the old red-sandstone.		
*4. After the deposition of the coal strata.	Immense faults, anticlinal axes, &c.	The great faults of Tynedale, the Penine chain, Craven, Derbyshire, Flintshire, South Wales, and generally of the coal districts.
Conglomerates follow in the red-sandstone.		
5. After the oolitic period.	Unconformity of stratification between oolite and chalk system.	Yorkshire, Dorsetshire.
*6. After the London clay.	Anticlinal axes and vertical strata.	Isle of Wight, Axis of the Wealden.

At the three epochs marked by stars, the most considerable movements and greatest changes in physical geography appear to have been produced. Such changes also occurred about the same epochs on the continent of Europe: the most universal of the phenomena seem to be the two earlier ones; but it is almost impossible in any case to prove that the occurrence of convulsions was synchronous at distant points. Since then we can neither affirm anything with respect to the change of force of the subterranean monuments at different geological epochs, nor can ascertain, except by reference to the phenomena of stratification and organic life, whether they occurred more frequently in one period than another, it is impossible to draw from the evidence of these disruptions any certain conclusion either as to the change of the earth's proper heat or the extent of geological time. If indeed the actual effects of earthquakes were to be placed against the mighty wall of the Penine fault, the vertical beds of the Isle of Wight, or the concealed dislocation of the coal-fields of Valenciennes, there would be no doubt of the decay of natural agencies; but this is not allowable, for the great dislocations alluded to are to be viewed as phenomena of a short interval of violent movements between long periods of ordinary action such as now obtains on the globe.

It may be supposed that the number of these cases of very great and extensive disturbance is in proportion to the time elapsed; but as none such has occurred within the reach of history for at least 4000 years, we see how very ancient is the earth; and further, we have no data for accurately computing in numbers the vast periods which have elapsed in producing the stratified crust changing many times its vegetable and animal races. On the whole, it appears that the day is not arrived for theory to trust itself with the attempt to assign definite values to the symbols of duration which remain in the earth. Long, undoubtedly, perhaps as long as the periods which the study of planetary motions has revealed, must be the whole range of geological time; but until we know at this day what is the average rate of deposition of sediment in the sea, or the usual age of marine *Mollusca*, until we can determine the numerical or structural relations between organic forms and physical conditions, or can convert the irregular effects of volcanic fires into a calculable series of changes of temperature, there is little hope that the invitation of the Royal Society, to assign the antiquity of the crust of the earth, will be accepted by prudent and competent geologists.

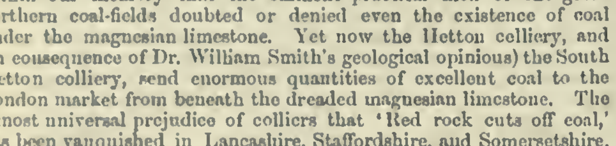
Economical Applications of Geological Science.—"Practice," says Professor Whewell, "has ever been the nurse of theory: art has ever been the mother of science, the comely and busy mother of a daughter of far higher and serener beauty. But the benefits are reciprocal; geology, at least, is capable of well repaying the large debt which it owes to the experience of the miner, the engineer, and the agriculturist, and indeed some of its truths are already largely productive of public benefit.

"There is hardly a district in this island where the reasoning of geology has not checked extravagant expenditure in search of coal or metallic ores where such are not to be found, and conquered the credulity of ignorance ever ready to listen to the delusive and almost superstitious notions of merely working colliers and miners. The false and deceitful promise of finding good coal by going deeper, will not often again lure the landed gentry and respectable companies to such adventures as sinking for coal in the oolites of Oxford, the sandstones of Sussex, or the silurians of Radnorshire. But it is not merely by preventing foolish and wasteful expenditure, in search of imaginary treasures, that geology has aided the mining interest: it is within our memory that the eminent practical men of the great northern coal-fields doubted or denied even the existence of coal under the magnesian limestone. Yet now the Hetton colliery, and (in consequence of Dr. William Smith's geological opinions) the South Hetton colliery, send enormous quantities of excellent coal to the London market from beneath the dreaded magnesian limestone. The almost universal prejudice of colliers that 'Red rock cuts off coal,' has been vanquished in Lancashire, Staffordshire, and Somersetshire, and reasons have been given by Conybeare and others for believing that under the red rocks of the midland counties great tracts of coal remain for the public advantage and the triumph of geology." ('Phil. Mag. and Annals.')

Some years ago, Lord Dartmouth, guided by geological reasoning, in opposition to the views of the local colliers, sunk a trial pit for coal near Birmingham, and found it below red-sandstone rocks. It was faulty near the pit bottom; but this has not prevented the establishment of a colliery, nor discouraged further attempts in the vicinity.

Coal-working.—In the practical department of coal-working, geology can as yet render little aid, because the experience of the coal districts has hardly yet been turned into science. The subject of the 'faults' ('troubles,' as they are often and justly called), from which no coal-field is exempt, and which by their effects on subterranean drainage, and the disarrangement of the subterranean works, their influence on the quality of the coal, and other circumstances, are of the highest importance to the collier, is yet almost wholly unknown as a branch of science. One general fact known concerning them (the correspondence of the dip of the fault to the depression of the strata), may be illustrated in the subjoined diagram after Professor Phillips's.

Fig. 8.



In this figure the faults *a*, *b*, and *x*, decline variously from the horizon *h h'*; and they are most frequently found to dip or decline under that portion of the divided strata which is relatively depressed, as *a* and *b*, not as *x*, which represents a rare and exceptional case. By the sides of faults the strata are often slightly or considerably bent, sometimes in the direction tending to unite their disrupted parts, as *a*; sometimes in the contrary way, as *b*. In the former case they are said to 'rise to an upthrow, and dip to a downthrow;' in the latter they 'rise to a downthrow, and dip to an upthrow.' If these circumstances were carefully recorded by surveyors of collieries, science might eventually combine the detached facts into general laws, shew their dependence on other conditions, and thus put an instrument of discovery into the hands of practical men.

It is a common thing to find valuable coal-beds at first injured, and ultimately rendered worthless, by the interposition of a wedge or band of rock, *r*, in some part of the thickness of the coal; thus the

Fig. 9.

High Main Coal of Newcastle is split, and in a particular direction ruined by the 'Heworth Band.' The upper part of the Great Staffordshire coal-beds goes off in 'the Flying Reed;' and the ten-feet bed of Barnsley in Yorkshire divides into almost unknown parts. If the details of colliery working were more completely recorded, the law of these phenomena could be more accurately traced, so as to answer the anxious questions which such intrusive bands suggest to coal proprietors.

The variations of quality in coal, whether of different beds in the same district (a common case), or of the same beds in different districts (as in South Wales, where good furnace coal is found in the east, and anthracitic coal abounds in the west), are not now known in a scientific form; and therefore science can give no help to practice. Nothing but the union of the parties interested in coal-working can furnish the data necessary for the establishment of general rules. [COAL-FORMATION.]

The beneficial results which mining operations have derived from geology are in proportion to the degree in which the experience of miners has been reduced to the form of science. On the subject of the situation of metallic treasures, already enough is known to show that the occurrence of mineral veins is a circumstance depending on conditions which are more or less ascertainable. For example, there is not, and perhaps has never been, in the British Isles, a single mine of any metal worked in any stratum more recent than the magnesian limestone; it is a general truth that rich veins of lead, copper, tin, &c., abound only in and near to districts which have been greatly shaken by subterranean movement; in Derbyshire, Alston Moor, Flintshire, and, in particular tracts, especially Cornwall and Devon, it is very apparent that near the great masses of granitic rocks the veins are most richly filled. The same facts are almost equally true on the continent of Europe, and in other parts of the world, though, occasionally, as in the Pyrenees, Auvergne, &c., the presence of igneous rocks may cause the exhibition of mineral veins in strata more recent than any of those which in England yield metallic ores.

In all cases where new mining ground is to be attempted, rules such as those above noticed are valuable; but even in districts partially known, or long worked, many problems occur which time and combined registration of phenomena observed might easily solve. These geological problems, as to the relation between the contents of a vein and the nature of the neighbouring rock, the occurrence of certain cross-veins, the depth of the workings, &c., usually present themselves to the practical miner under the general question of the probability of the vein being productive, and though the mining experience of 2000 years has been found insufficient to answer it, there appears no reason to doubt that it is capable of solution by the progress of geology. It is known that in a country of limestone, gritstone, and shale, equally broken by the same fissures, the former is generally most productive of lead (Alston Moor); that certain porphyritic rocks in Cornwall and Saxony appear directly influential on the deposits of particular metals; that argentiferous lead ore is more frequent in primary than in secondary strata; salts of lead more plentiful in the upper parts of veins (Lead Hills, Caldbeck Fells); but the precise nature of the connection of the phenomena is yet a desideratum, and it will be long ere the dim and wavering light of experience can be replaced by the steady beams of the torch of science. In the recent discoveries of gold in California and Australia we have an instance in which geological knowledge pointed successfully to these districts as being likely to contain the precious metal. [MINERAL VEINS.]

In planning the lines of railways, canals, or common roads, the engineer will often be benefited by the records of geological surveys. In looking at the geological map of England, for example, it must be evident to any one acquainted with the geographical characters of the different formations, that no canal can be made from London to the western or north-western counties without a tunnel or summit level on the chalk hills (as at the Kennet and Avon, between Wilton and Devizes, and on the Grand Junction, at Tring). The oolitic range of hills, with its basis of lias, presents a similar and parallel obstacle, conquered by tunnels on the Thames and Severn at Shepperton, the Oxford Canal at Claydon, the Grand Junction at Braunston and Blisworth.

Since then these and other ranges of hills compel the formation of summit levels and tunnels, it is of importance that the whole of a country should be known to the engineer, as to its mineral structure as well as its elevation, in order that the situation of these may be properly fixed. It was inconvenient to make the Thames and Severn tunnel at its present level, often much above the level of the spring which is called the source of the Thames, and in the thirsty oolitic rocks; for thus the cost of maintaining the supply of water by puddling the canal, and engines for pumping, has been found very oppressive. Tunnels and summit levels for canals should certainly be made in argillaceous rocks, and geological investigations will often point out situations where, from particular displacements of the rocks, this is practicable, even in a range of hills so continuous and so calcareous as the chalk or the oolites.

The same rules do not apply to railroads, which, on the contrary, may often be beneficially carried through dry rocky hills which would absorb all the water of a canal.

In the execution of the works of canals and railroads, a good geological map would often be found more serviceable as a guide to the engineer than a great number of borings, unless these were placed in situations corresponding to the variations of the strata, which such a map would indicate.

In some favoured countries the labours of the sculptor and the architect are scarcely injured by exposure to the atmosphere for 2000 years; while in our damp and changeable climate even the interiors of cathedrals show, by the decay of their marbles and the destruction of the stone walls, the necessity for an architect to study the durability of his materials. It is remarkable that the Romans were more prudent or more fortunate in their choice of stone for buildings in Bath and York than their successors have been. The relics in the Institution at Bath abundantly prove that the rag beds of the oolite are more durable than the finer and handsomer freestone which the enterprise of Allen first introduced to common use. The magnesian limestone in the Roman walls of York is in far better condition of preservation than most of that which is of only half the age in the face of the cathedral.

The Saxons in the north of England used the coarse and durable millstone-grit, which on the brows of the high mountains of Derbyshire and Yorkshire stands conspicuous for its bold defiance to the elements. In choosing from any given rock the parts which are most fitted for permanent edifices, the examination of nature is perhaps more instructive than even a study of buildings. Not every sort of water exists in the deeper parts of the earth, and in fact fills the whole space left by fissures in the rocks, unless where, as in diagram, *fig.* 10, there be a fault which breaks the continuity of the communications along the rocks. At the surface there will be generally one or more springs (*z*) along the line of such fault, F.

In sinking deep pits it is generally found that argillaceous strata are quite dry within; for example, in the diagram above referred to, the well *a*, supposed to be sunk in the London clay, yields no water; but the other strata, alternating with the clays, yield water in greater or less quantity, and of quality corresponding with the nature of the rock. Thus the well *b*, sunk down to the sands, lignites, &c., of the plastic clay, yields some water, not always of good quality; but when the well, as *c*, is made to reach to and penetrate the chalk, a great body of good water commonly rises from that rock. [WATER; ARTESIAN WELL, in ARTS AND SC. DIV.]

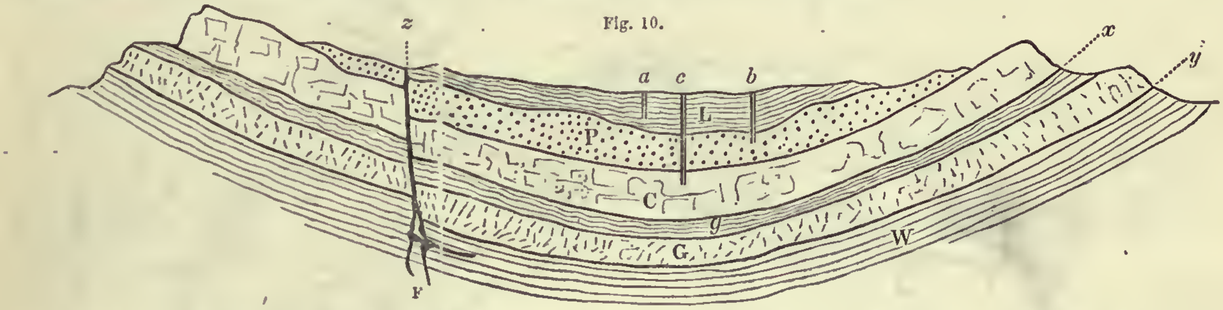
To drain land is to intercept the natural springs: this can never be done upon good principles unless the geological structure of the district be known. When porous rocks alternate with strata impervious to water, the springs will commonly issue at several points on the surface-line of junction of the strata, as at *x* and *y* in diagram, *fig.* 10; and by making a deep drain along the line of junction, Dr. Smith has often accomplished the complete desiccation of wet lands in the oolitic districts of England, which had been in vain guttered in all directions by the usual hollow drains.

The same principle applies, but not with the same ease of success, to the draining of districts where gravel and clay are much intermingled. The gravel acts as a porous rock, but its irregular distribution renders the operation of deep draining costly and less effectual.

From the same principles it follows that springs may be regulated, and the subterranean reservoirs employed to store up water in the winter, when it is little wanted, for the purpose of supplying the demand in summer. This has actually been done by Dr. W. Smith, who opened, in the sandstone rocks near Scarborough, a subterranean reservoir on the site of a little spring, closed it with a dam, and regulated the discharge for the benefit of the town. [SPRINGS.]

(Lyell, *Principles of Geology*; Lyell, *Elementary Geology*; Ansted, *Geology, Introductory, Descriptive, and Practical*; Ansted, *Elementary Course of Geology*; Phillips, *Guide to Geology*; Jukes, *Popular Physical Geology*; De la Beche, *How to Observe in Geology*; Portlock, *A Rudimentary Treatise on Geology*.)

Fig. 10.



a, *b*, *c*, wells; L, London clay; P, plastic clay and sands; C, chalk; *g*, gault; G, lower greensand; W, wealden; *x*, *y*, *z*, springs; the last at a fault, F.

granite resists the carbonic acid and moisture of the air; but while the rolled blocks from Shap-Fell retain, after thousands of years' exposure on the surface, their surfaces of attrition, the granitic top of Castle Abhol, in Arran, is so rotten that it may be easily beaten to fragments by a hammer. The millstone-grit of Brimham is almost wasted away over a hundred acres, while that of Agra Crags appears to be more capable of withstanding the same agencies; and the Druidical stones of Boroughbridge have stood the storms of 2000 years, with little more injury than a few rain-channels which scarcely reach the ground.

To the agriculturist geology has rendered some services, and probably may in future be appealed to for further aid. Lister's proposal for the construction of a map of soils was only partially executed, after a century, in some of the county reports made to the Board of Agriculture. The principal use, as it appears to us, of such a map (and this is in fact supplied by the maps of strata), is to aid the statistics of agriculture by furnishing a basis for comparing the agricultural practices on similar and dissimilar soils.

But geological science will appear more intimately connected with agricultural improvements if we consider it as the basis of all sound knowledge of springs and the subterranean distribution of water. The rain which falls from the heavens upon all soils and rocks indifferently, runs off the clays, but sinks into the limestones, sandstones, and other rocks, whose open joints act like so many hidden reservoirs. Owing to the complicated intercommunication of the fissures, these reservoirs are slowly filled and slowly emptied; both the supply from rain and the discharge from springs may and generally do go on together; and the jointed rocks may be viewed as equalising the supply and expenditure.

But below the level of the springs thus formed, a great body of

GEOMALACUS (Allman) a genus of Molluscous Animals belonging to the family *Limacidæ*. [LIMACIDÆ.]

GEOMYS. [MURIDÆ.]

GE'OPHILA (from γῆ, the earth, and φιλ, love), a genus of Plants belonging to the natural order *Cinchonaceæ*. It has the limb of the calyx 5-parted, with linear spreading segments; the corolla tubular, with a pilose throat and 5 rather recurved lobes, with 5 anthers inclosed; the stigma bifid; the berry ovoid, angular, crowned by the calyx, 2-celled, 2-seeded.

The species are creeping herbaceous plants with stalked cordate leaves, like those of a violet; the stipules are solitary, undivided; the flowers sub-sessile, umbellate, surrounded by bracts, which are shorter than the flowers.

G. reniformis has the petioles hairy above; reniform obtuse leaves, with the lobes at the base approximate; the bracts linear; the peduncles 4-6-flowered, shorter than the leaves. It is a native of moist shady places in the hotter parts of America, as Havanna, Jamaica, Puerto Rico, Brazil, and the basin of the Orinoco. The root of this plant is emetic, and may be used with advantage as a substitute for ipecacuanha.

G. violacea has cordate reniform leaves, obtuse, glabrous, with the lobes approximate at the base; petioles hairy above; umbels few-flowered, almost sessile between the ultimate pair of leaves; bracts linear-lanceolate. It is a native of Guyana, in woods, and of the Isthmus of Panama. It differs from *G. reniformis* by the petioles being shorter, the umbels hardly pedunculate, the corollas violaceous, and the berries blue.

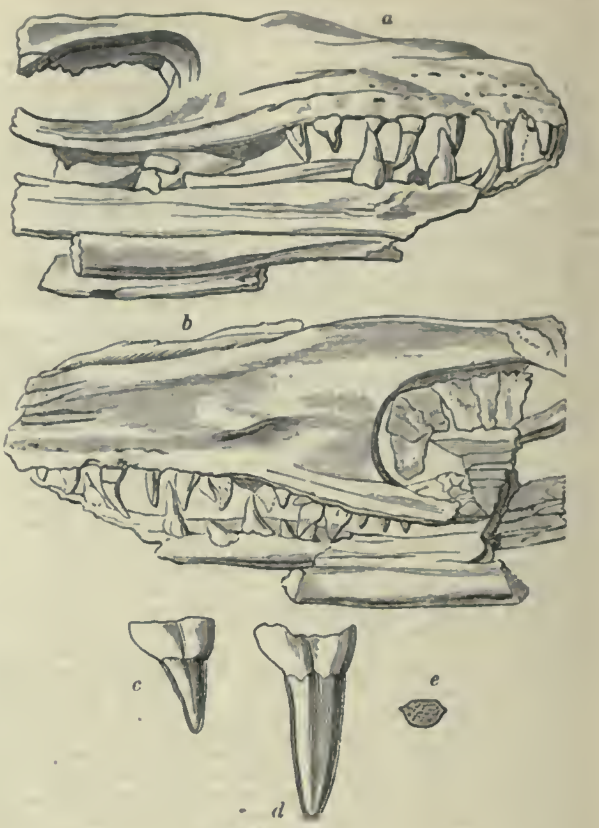
There are several other species of this genus, all of which were formerly referred to the genus *Psychotria*. They are *G. diversifolia*, *G. violæfolia*, *G. macropoda*, and *G. gracilis*.

GEOPHILUS. [COLUMBIDÆ.]

GEORGI'NA, a name sometimes given to the Dahlia, but improperly.

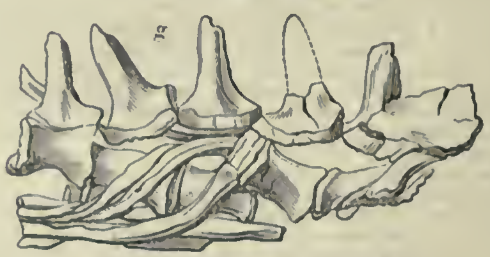
GEO'RYCHUS, Illiger's name for the Lemmings of Cuvier. [MURIDÆ.]

GEOSAURUS, Cuvier's name for a sub-genus of Saurians, found in a fossil state only, and considered by him as intermediate between the Crocodiles and the Monitors. The remains of this animal were first obtained from the white lias at Monheim, in Franconia, by Sömmering, and named by him *Lacerta gigantea*. In a paper in the 'Nova Acta physico-medica Academiæ Cæsareæ Leopoldino-Carolinæ Naturæ Curiosorum,' Dr. Ritgen has proposed a new name for this with several other fossil animals. On this paper a writer in the 'Zoological Journal' has the following remarks:—"The first of Dr. Ritgen's animals is the *Lacerta gigantea* of Sömmering, *Mosasaurus* of Conybeare and Parkinson, for which Dr. Ritgen, without assigning a single reason for the change of name, is pleased to adopt the more than sesquipedalian title of *Halilimnosaurus crocodiloïdes*. This appellation however may serve, in some degree, to explain his views of its affinities and original habitation, inasmuch as it shows that he regards it as a lacertine animal resembling a crocodile and inhabiting salt-water marshes, intermediate therefore between the extinct *Enaliosauri*, or Sea-Lizards, and the living Crocodiles of fresh-water streams. It is, moreover, the *Geosaurus* of Cuvier's 'Ossemens Fossiles.' There is some little obscurity here, which we will endeavour to dispel. That Cuvier's name, *Geosaurus*, should be retained according to the laws of nomenclature, there can be no doubt; and it appears that this provisional name was given, not in reference to the habits of the extinct lizard, but, to use Cuvier's own words ('par allusion à Terre, mère des Géans')—by an allusion to Terra, the Earth—Ge (Γῆ) of the Greeks, the fabled mother of the Giants. Indeed the sclerotic plates still remaining in the portion of the cranium figured by Cuvier in his 'Ossemens Fossiles,' could not have escaped the observation of that acute zoologist (who was so eminently alive to the laws of co-existence), as indicating aquatic habits. That he considered it subgenerically different from *Mosasaurus* appears from the following observations: Immediately after the allusion to the origin of the name, Cuvier says, 'I cannot retain for it the epithet *Giganteus* (Je ne peux lui laisser l'épithète gigantesque); for, in the great genus *Lacerta* we have already the animal of Maestricht, or *Mosasaurus*, which greatly surpassed it, and there is also another (the *Megalosaurus*) which is very superior in size—(nous avons d'abord l'animal de Maestricht, ou *Mosasaurus*, que le surpasse de beaucoup, et nous allons en voir un autre—le *Megalosaurus*—qui lui est aussi très supérieur).'"



Again, in a note to the previous article in the 'Ossemens Fossiles,' on *Mosasaurus*:—"With regard to the fossil animal of Monheim (*Geosaurus*), which M. de Sömmering has also regarded as identical with that of Maestricht (*Mosasaurus*), we shall see in a succeeding article that it differs from the Maestricht animal in many respects. M. Hermann von Meyer, in his most useful work 'Palæologica zur Geschichte der Erde und ihrer Geschöpfe' (8vo. Frankfurt, 1832), widely separates the two sub-genera. The first, *Geosaurus*, he exemplifies by *Geosaurus Sömmeringii*, syn. *Lacerta gigantea*, Sömmering, *Halilimnosaurus crocodiloides* of Ritgen. The second, *Mosasaurus*, Conybeare, *Saurochampsa*, Wagler, he exemplifies by *Mosasaurus Camperi*, syn. *M. Hofmanni*, *Lacerta gigantea*, Sömmering, zum Theil (in part). In his 'System der Fossilen Saurier,' which fossil Saurians he divides into four sections, denoted by the letters A, B, C, and D, he places *Geosaurus* under section A—(Saurier mit Zehen ähnlich denen an den lebenden Sauriern), and *Mosasaurus* under section C—(Saurier mit flossartigen Gliedmassen)."

The remains upon which Cuvier founded his sub-genus were found in the canton Meulenhardt, at the depth of 10 feet, and a few paces from the crocodile described by Cuvier (Gavial of Monheim and of Boll; 'Oss. Foss.' tom. v. pp. 120-125; *Crocodilus priscus* of Sömmering; *Æolodon priscus* of Hermann von Meyer), by the labourers employed to work the mines of granular iron (fer en grains) which fills the fissures of the strata of calcareous schist.



Geosaurus Sömmeringii. (From Cuvier's figures.)

a, *b*, part of the head, which has been compressed; some of the sclerotic plates are still left within the orbit, as seen in Fig. *b*; *c*, *d*, *e*, teeth which had preserved their hard shining brown enamel; *f*, *g*, vertebræ; *f* exhibits a part of the column; near the last vertebræ are the remains of the pelvis and femora; *g*, five vertebræ like the first of those in Fig. *f*. Fragments of ribs in disorder are seen near both sets.

Sömmering, to whom the Count of Reysach gave these precious fragments, to use Cuvier's expression (for in consequence of the nature of the bed in which they were discovered they were not well preserved), published an accurate account of them in the 'Memoirs of Munich' for 1816, accompanied by a lithographic illustration, which Cuvier reduced, and published in his 'Ossemens Fossiles;' Sömmering however thought that the bones belouged to a youug individual of the Maestricht animal (*Mosasaurus*.)

The boues were nearly calcined. Near the remains of the Sauriau were a flat ammonite 4 inches in width, a fragment of bluish shell, and a great quantity of small scales, which, according to Sömmeriug's conjecture, belonged either to fishes or perhaps to the animal itself, if it was a Monitor, or some other lizard witb small scales.

The localities given by Hermanu von Meyer are the Flötz; Solenhofen slate (Schiefer von Solenhofen); and, with reference to another specimen (with a query), for which he refers to Dekay, 'Ann. of the Lyc. of New York,' vol. iii., the marl of the Greeusaud iu New Jersey (Mergel des Grünsandes iu New Jersey).

The original specimens figured and described by Sömmeriug are now in the collection of the British Museum (Wall-case A. B., 'Mantell Fossils of the British Museum,' p. 175).

GERANIACEÆ, *Cranesbills*, a natural order of Exogenous Plants, consisting chiefly of herbaceous plants or shrubs. They have tumid stems separable at the poiuts. The leaves are either opposite or alternate; in the latter case opposite the peduncles, with membranous stipules. The flowers are white, red, yellow, or purple. The sepals 5, persistent, ribbed, more or less unequal, with an imbricated æstivation, sometimes saccate or spurred at the base. The petals 5, seldom 4, in consequence of one being abortive, unguiculate, twisted in æstivation, equal or unequal, either hypogynous or perigynous. The stamens usually mouadelphous, hypogyuous, twice or thrice as many as the petals; some occasionally abortive. The ovary composed of 5 carpels, placed round a long awl-shaped torus or growing poiut, each 1-celled, 2-seeded; styles 5, cohering round the torus, aud separable from it; ovules semianatropal, adhering to the torus. The fruit formed of five shells, coheriug round a long beaked torus, each piece containing one seed, having a membrauous pericarp, and terminated by au indurated style, which finally curls back from the base upwards, carryiug the pericarp along with it. The seeds solitary, without albumen. The embryo curved and doubled up, the radicle pointing to the base of the cell; cotyledons foliaceous, convolute, and plaited. The long beak-like torus round which the carpels are arranged, and the presence of membranous stipules at joints which are usually tumid, are true marks of this order, and all plants not possessing these peculiarities must be excluded. Among them is a South Americau genus called *Rhynchotheca*, which has been even elevated into a natural order, but which, according to Lindley, is surely an oxalid without petals, for the beak observed in its fruit belongs to the carpels and not to the torus. It is clear that in this order the ovules do not spring from the margins of the carpellary leaves. The species, about 500 in number, are very unequally distributed over various parts of the world. A great propotion is found at the Cape of Good Hope, chiefly of the genus *Pelargonium*. *Erodium* and *Geranium* are chiefly natives of Europe, North America, and Northern Asia. *Pelargonium* is found in Australia. An astringent principle and an aromatic or resinous flavour are the characteristics of the order. *Geranium* aud *Erodium* are used in medicinc. *Pelargonium* is remarkable for its beautiful flowers; it is nevertheless astringent in its properties. The affinities of *Geraniaceæ* are with *Balsaminaceæ*, *Oxalidaceæ*, aud *Tropæolaceæ*. (Lindley, *Vegetable Kingdom*.)

Geranium pratense.

1, a magnified calyx, in the centre of which is the rostrum, or beak, from which the cocci are rolling back.

GERA'NIUM, Cranesbill (from γέρανος, crane; the long beak which terminates the capsules resembles the bill of a crane), a genus of Plants the type of the natural order *Geraniaceæ*. The flowers have 5 petals and 5 sepals, 10 monadelphous stamens, alternately larger, and with glands at their base. There are 79 species of this genus enumerated, of which 13 are British; of these ouly two are applied to any useful or medicinal purpose.

G. Robertianum has 2-flowered peduucles; obovate, entire, or slightly emarginate petals; very long glabrous claws; transversely wrinkled downy capsules, smooth seeds, ternate agrimate leaves, and stalked trifid inciso-pinuatifid leaflets. This plaut has small bright crimson flowers, and is found on waste ground, walls, and banks in Great Britain, in Brazil, and Chili. The whole herb has a strong disagreeable smell, which is said to be a preventive against bugs. A decoction of the plant is recommended as likely to give relief in calculous cases. It contaius tannin, and exerts an astringent action on the system, and is given to cattle in some diseases.

G. maculatum, Spotted Crauesbill, has a rather angular stem covered with retrograde pubesceuce; 3-5-parted leaves with deeply-toothed lobes; obovate entire petals; the filaments of the stamens hardly ciliated at the base. This species is a native of North America, from Canada to North Carolina. The flowers are of a pale lilac colour. On account of the astringent nature of this plant, it is known in some parts of North America as Alum-Root, and is employed successfully as a remedy iu dysentery among children, a disease very prevaleut in the parts of the country where it grows. The tincture is recommeuded in cases of ulcerated sore-throat aud soreness of the gums, &c. Dr. Bigelow discovered the presence of large proportions of tanuin and gallic acid in this plant. The quantity of tanniu appears to be greater thau that of any other constituent.

The other British species are :—

G. phæum has 2-flowered peduncles, roundish wedge-shaped petals, rather longer than the mucronate sepals; carpels hairy below, transversely wrinkled above; seeds punctate, striate. It is found in woods aud thickets, rarely.

G. nodosum has obcordate long petioles, awned sepals, even downy carpels; leaves 3- to 5-lobed, lobes ovate, acuminate, serrate. It is fouud iu Cumberlaud aud Hertfordshire.

G. sylvaticum has 2-flowered peduncles, obovate slightly-notched long petals, awned sepals, dotted seeds, palmate 7-lobed leaves. The filaments of the stamens subulate, fruit-stalks erect.

G. pratense has 2-flowered peduncles, the carpels even, hairy, the hairs spreading, glaudular; seeds minutely reticulated; the filaments of the stamens filiform, with a triangular ovate base; the fruit-stalk deflexed.

G. sanguineum has peduncles mostly single-flowered; carpels smooth, crowned with a few bristles; leaves nearly round, 7-lobed; stem diffuse, hairy—the hairs spreading horizontally.

G. pyrenaicum has obcordate petals, twice as long as the mucronate sepals; claws densely ciliated; stem erect, villose.

G. pusillum has bifid petioles, about equalling the mucronate sepals; claws slightly ciliated; carpels with adpressed hairs; seeds smooth; stem diffuse, downy.

G. dissectum has smooth carpels with erect hairs, reticulated seeds; stem diffuse, hairy; leaves divided almost to the base, louger than the peduncles.

G. columbinum has obovate emarginate petioles, ciliated claws; the carpels smooth, with a few minute scattered hairs; the peduncles longer than the leaves; pedicels very long.

G. rotundifolium has spathulate petals, entire, obtuse, rather longer than the shortly-awued sepals; claws glabrous; carpels smooth, with spreading hairs; seeds reticulated.

G. molle has oblong deeply-bifid petioles, ciliated claws; carpels transversely wrinkled, glabrous; seeds smooth; flowers small and purple.

G. lucidum has obovate entire petals; claws glabrous, very long, uearly equalling the transversely rugose pyramidal calyx; carpels reticulated, triply keeled.

G. tuberosum, a plant growing in the south of Europe, particularly in Italy and Silesia, is the γεράνιον of Dioscorides (iii. 121), and the *Geranium tertium* of Pliny (xxvi. 11).

The hardy perennial kiuds of *Geranium* are very beautiful plants, and well adapted for ornamental cultivation. They will thrive iu any common garden soil with ordinary care.

(Don, *Dichlamydeous Plants*; Babington, *Manual of British Botany*; Fraas, *Synopsis Plantarum Floræ Classicæ*.)

GERBILLUS. [MURIDÆ.]

GERFALCON. [FALCONIDÆ.]

GERMEN. [PISTIL.]

GERMINA'TION, the first growth of a seed, the act by which it exchanges the conditiou of an embryo for that of a young plaut. The embryo of a plaut is folded up in the inside of a seed, and is either a short double cone on which two or more cotyledons are fixed, or a simple more or less cylindrical body having no apparent distiuction between the cotyledons and the axis. [SEED.] It has moreover little other than a cellular organisation, very often not possessing a trace of the complicated vascular and tubular structure afterwards developed. The act of unfolding, breaking through the integuments of the seed, and acquiring a vascular and tubular as well as cellular organisation, is germinatiou. When a seed is placed in a moist situation sufficiently warm, and with access to air, the following phenomena, according to the researches of De Saussure, and the more recent ones of Boussingault, take place:—1, absorption of oxygen from the atmosphere; 2, a disengagement of carbonic acid; 3, a disengagement of ammonia; 4, conversion of starch into dextrin, gum, sugar, &c.; 5, increase in bulk—growth of the embryo.

All these phenomena were supposed to be connected with the growth of the embryo, and the absorption of oxygen and the disengagement of carbonic acid gas were regarded as an act of life and as necessary to the process of germination. From this point of view germination and vegetation, the growth of the plant, were stated to be antagonising processes; the one being a respiratory, an oxidating process; the other a decomposing, a deoxidating process. At the same time the albumen of the seed was regarded as the sole source of nutriment for the growing tissues of the young plant. In a paper read at the meeting of the British Association, July, 1845, Dr. Lankester proposed a new theory of the phenomena of germination. It is obvious that the only essential process of germination is the growth of the young plant or embryo. The process of development of the embryo from primitive cytoblasts, is precisely the same as that of every other part of the plant, and from an identity of structure Dr. Lankester inferred there must be an identity of function. But the ordinary theory of germination gives a different function to the tissues of the embryo from that of the other parts of the plant. This Dr. Lankester considers unnecessary, and attributes the absorption of oxygen, and the disengagement of the carbonic acid gas and ammonia, to the result of the decomposition of the starch and protein contained in the perisperm of the seed, whilst the growing cells of the embryo appropriate the carbonic acid and ammonia with water, just in the same way as all other cells in the vegetable kingdom. The facts by which this theory is supported, and which are not explained by the old theory are, as follows:—

1. In many plants there is little or no perisperm or albumen developed, and the conditions required for germination are those of vegetation.

2. Many plants with horny and hardened perisperms, as the *Phytelephas macrocarpa*, the *Phœnix dactylifera*, and species of *Bactris*, *Cocos*, and *Astrocaryum*, germinate, without consuming any appreciable quantity of the perisperm.

3. The quantity of carbonic acid obtained by De Saussure varied not according to the number, but according to the mass of the seeds, proving that it arose from the decomposition of the starch as a chemical process, and not from the growth of the embryo as a process of life.

4. De Saussure found that the relation between the oxygen consumed and the carbonic acid gas given out was different in different plants, but this relation ought to be constant if the theory of oxidation or combustion during germination be correct.

5. Boussingault observed that the changes supposed to be peculiar to germination went on in the perisperm after the young plant had developed its radicle and plumule, and was capable of an independent existence.

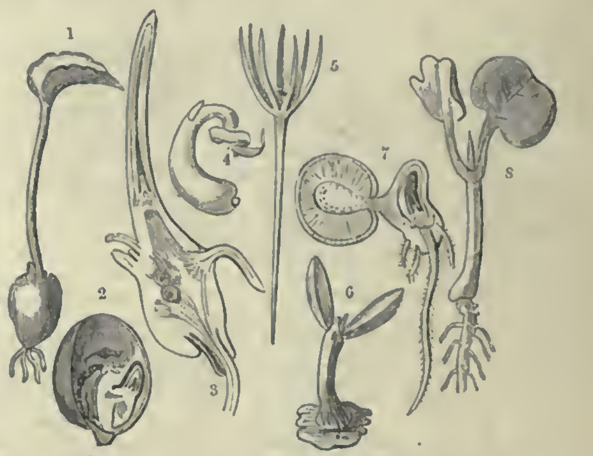
6. The changes which take place in the chemical composition of the perisperm of the seed during germination can be artificially produced by mixing starch and protein (diastase) together, and exposing them to the action of the atmosphere.

This theory modifies the view which is mostly taken of the use of the albumen. It does not appear to be deposited entirely for the use of the young plant, but in many cases is merely an organ of support, and bears the same relation to the embryo that the wood of a branch does to the buds which grow upon it.

The progress of development in the embryo is usually first for the radicle to lengthen, then for the cotyledons to unfold, and then for the plumule to extend into a stem (*fig.* 8); but in Endogens, the plumule of which is often inclosed in the very substance of the cotyledon, a somewhat different process takes place.

In *Potamogeton lucens* (*fig.* 4) the radicle generally swells and lengthens, and at last produces from within its apex a papilla which becomes the root; the cotyledon, which is spiral, at the same time lengthens, and at last the plumule pierces through one side of the embryo. In *Canna Indica* (*fig.* 7) the cotyledon always remains inclosed in the albumen, merely swelling; the radicle and cauliculus are protruded from the seeds; the former turns downwards and emits a number of fine roots, the latter produces from within its substance a conical body, consisting of several sheaths one within the other, which are the rudiments of leaves. The Cocoa-nut differs from *Canna* chiefly in its cotyledon swelling exceedingly and becoming spongy, filling the whole cavity of the seed, and absorbing the milky fluid. Grasses offer only a slight modification of the same form. The embryo of maize, when divided vertically (*fig.* 2) appears like a fleshy plate lying on one side of the flowery albumen; at its back next the albumen is the cotyledon, next the skin is a cone of sheaths (as in *Canna*) forming the plumule, and at the base of the plumule another cone constituting the radicle. When such an embryo germinates, the radicular cone pierces the soil, emitting from its interior, through a kind of sheath, a few slender roots, and protruding others from its surface; and the other cone, representing the plumule, at the same time lengthens upwards in the form of a green spire, leaving the original external part of the sheath at its base (*fig.* 3).

Many anomalies in the development of the embryo of both Exogens and Endogens might be pointed out, but they are of little interest to any but professional botanists. Among the most striking are the following:—In the genus *Pinus* the cotyledons are numerous, and placed in a whorl (*fig.* 5); in the *Cyclamen* the cauliculus enlarges into a roundish turnip-like mass, from the apex of which spring the leaves and flowers, and from the base the roots (*fig.* 1); in mistletoe, a parasitical plant (*fig.* 6), the radicle becomes a flat plate, concave on the under side, by which it adheres to the bark of the plant it grows upon, and from which the singular roots proceed, which eventually insinuate themselves through the bark between the plates of living wood.



The manner in which the radicle protrudes itself is different in Exogens and Endogens. In the former its point gradually lengthens and becomes a new root; this is called 'exorhizal' germination: in the latter the point of the radicle opens and allows the true root to escape from within it, a phenomenon to which the term 'endorhizal' is applied.

Attempts have been made to expedite the process of germination by steeping seeds in a weak solution of chlorine, but no practical advantage has been derived from the experiment. A more effectual plan has been found for hard-shelled seeds, such as those of the *Acacia*, namely, boiling the seeds for a period between one and five minutes. This has certainly, in some cases, had the effect of causing seeds to grow which under ordinary circumstances would not have grown; a circumstance to be ascribed, we conceive, to the hard integuments of the seed being so much softened as to offer no great resistance to the attempts of the embryo to escape from within them, —attempts which required no assistance when the embryo was in full activity and the seed-coat comparatively soft, but indispensable when these conditions are reversed by the loss of vigour in the embryo and the excessive induration of the case containing it.

GERVILLIA, a genus of Molluscous Animals belonging to the *Conchifera*, or Bivalves, hitherto only found in a fossil state. M. Defrance first noticed the genus, which he named after M. de Gerville, who discovered in the Baculite Limestone of Normandy the species on which the genus was established. M. Deslonchamps ('Mémoires de la Société Linéenne de Calvados,' 1824) proposed several modifications of the character, so as to allow the genus to embrace four other shells in addition to the first-described species, *Gervillia solenoides*, viz.:—*Gervilliæ pernoides* (*Perna aviculoides*, Sow., 'Min. Con.,' t. 66), *Siliqua*, *monotis* and *costatula*, which are figured and described in the memoir. M. Defrance thought that the bivalve was furnished with a byssus, but M. Deslonchamps conceives that *Gervillia* has no opening for the passage of that appendage. "Should this prove to be the case," writes the reviewer of the memoir ('Zool. Journ.,' vol. i.), "which we are rather inclined to doubt, it will effectually separate the shells of this from those of the other genera of the *Malleaceæ*. Their nearest affinity is with those of *Perna*, from which they may be at once distinguished by possessing an apparently inner additional hinge, formed of several oblique teeth, variously disposed, according to the species." Mr. G. B. Sowerby ('Genera of Recent and Fossil Shells,') who judges the genus to have been marine from its associates, and who states that there is good reason for presuming that it was adherent by a byssus, gives the following:—

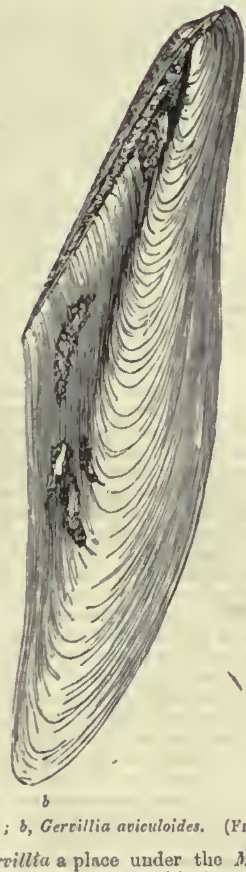
It has the following characters:—Shell oblong, nearly equivalve, very inequilateral, and oblique; hinge-line rather long, linear, nearly straight, with many irregular rather transverse little pits, and teeth placed below the dorsal edge.

Mr. Sowerby regards it as an intermediate genus between *Avicula* and *Perna*. It resembles, he observes, the former in its general form and external appearance; whilst its hinge is somewhat like that of the latter, though sufficiently different to enable us to point out without difficulty the peculiarities by which it may at once be known.

Cuvier, in his last edition of the 'Règne Animal,' places it under Les Pernes (*Perna* of Bruguières), between *Crenatula* and *Inoceramus*.

M. De Blainville arranges the genus under his family *Margaritacea* (the third of his *Acephalophora Lamellibranchiata*), between *Pulvinites* and *Avicula*. He notices that the shell gapes anteriorly, perhaps for the passage of a byssus, and describes the ligament as multiple and inserted in many conical fossæ forming a row within the hinge. He also describes the abdominal impression as single, and as rather anterior.

a



b

a, Gervillia solenoides; b, Gervillia aviculoides. (From Sowerby's Genera.)

M. Rang gives *Gervillia* a place under the *Malleaceæ* of Lamarck, between *Malleus* and *Inoceramus*. In his description he notices the slight anterior opening as being doubtless ('sans doute') for the passage of a byssus.

M. Deshayes, in his edition of Lamarck, notices the memoir of M. Deslonchamps, speaks of the multiple ligament and the single somewhat oval muscular impression placed towards the middle of the length of the shell and on the side of the dorsal edge, and remarks that, like the *Pernæ* and other genera of the family *Malleaceæ*, the *Gervilliæ* are covered externally with a delicate layer of fibrous matter, and that they may be regarded as *Pernæ* with an articulated hinge. The place assigned to them by M. Deshayes is between *Perna* and *Catillus*.

Mr. G. B. Sowerby observes that many species have occurred at various geological periods from the Lias upward to the Baculite Limestone of Normandy. M. De Blainville mentions the species as found in the department of La Manche. The genus occurs in the Cretaceous Group (Greensand), and largely in the Oolitic Group.

GERVI'SIA (Zoology), a name given by Messrs. Quoy and Gaimard to a genus of small Mollusks approximating nearly to *Pleurobranchus*.

GESNERA'CEÆ, *Gesnerworts*, a natural order of Monopetalous Exogens, allied to *Scrophulariaceæ*, and with them forming a portion of the Dicarpous group. They are principally characterised by having an ovary more or less inferior, and a parietal placentation. The leaves are rugose, without stipules, generally opposite or whorled. Flowers in panicles or racemes, seldom solitary. The calyx is half-adherent, 5-parted, with a valvate or open æstivation. The corolla monopetalous, tubular, more or less irregular, 5-lobed, with an imbricated æstivation. Stamens 2 or 4, didynamous; anthers often cohering, 2-celled, innate, with a thick tumid connective; the rudiment of a fifth stamen is present. Ovary half-superior, 1-celled, with 2 fleshy 2-lobed parietal polyspermous placentæ placed right and left of the axis, surrounded at its base by glands or a fleshy ring; style continuous with the ovary; stigma capitate, concave. Fruit capsular or succulent, superior, 2-celled, with 2 opposite lateral placentæ, each consisting of 2 plates. Seeds very numerous, minute; embryo erect in the axis or fleshy albumen, with the cotyledons much shorter than the radicle; testa thin, with very close fine oblique veins, sometimes extended into long hairs, or even flattened into a wing. They inhabit the hot and damp parts of South America, and in some cases overrun trees with their rooting stems in the manner of ivy. The prevailing colour of their flowers is scarlet; some however are purple, as the Gloxinias, and others pale-green, as *Sinningia* and *Drymonia*. Many beautiful kinds are known in our gardens; and several other magnificent species are figured in Von Martius's 'Nova Genera et Species Plantarum,' vol. iii.

Leaves and flowers of *Gesnera grandis*.

1, a corolla laid open to show the interior; 2, a calyx, with the projecting style; 3, a transverse section of a capsule.

GEUM, a genus of Plants belonging to the natural order *Rosaceæ*. It has a flat permanent calyx; a limb in 10 acute deep segments, 5 alternate ones much the smallest. Petals 5, rounded, undivided, or cloven, attached by their claws to the rim of the calyx opposite to its smaller segments, being about equal to the longer ones. The filaments are numerous, awl-shaped from the rim of the calyx, shorter than the corolla. Carpels superior, ovate, compressed, very numerous, in a round head. Styles long, lateral, with a joint above the middle; lower part permanent, upper deciduous. Stigmas simple. Achenia ovate, compressed, hairy, each with a long lateral tail, formed of the enlarged hardened lower part of the style, terminating in a hook. Receptacle cylindrical, dry, hairy, seated on the permanent reflexed calyx.

G. rivale, Water-Avens, is found in meadows and woods throughout Europe, and in Great Britain. It has a root somewhat woody, blackish, creeping, and running deep into the ground; astringent, with the flavour of cloves. The herbage is hairy, and of a deep green. The stem from 8 to 12 inches high, slightly panicled, otherwise simple. The radical leaves are stalked, their terminal lobe very large, rounded, lobed, and sharply crenate. The stem-leaves are few, stalked, ternate, or 3-lobed; stipules of the latter ovate, acute, cut, purplish. The flowers are almost pendulous, singularly elegant, growing upright as the fruit ripens. The calyx of a rich purplish-brown, erect, subsequently reflexed. The petiole is erect, cloven, and of a tawny brown. It is considered to be a stomachic, and is said to be useful in diarrhœa, and is also employed in the United States in diseases of the bladder.

G. urbanum, Wood-Avens, is common in Great Britain and throughout Europe. The root consists of many stout brown fibres, astringent, and in some degree aromatic; it is said to give an agreeable flavour to beer, and even to wine. The stem is 2 feet high, erect, round, rough, and finely hairy; branched at the upper part, bearing several flowers. The radical leaves are on long stalks, interruptedly pinnate, somewhat lyrate; the odd leaflet rounded, often deeply 3-lobed. Stem-leaves ternate, stalked; upper ones simple, 3-lobed, wedge-shaped; all variously notched and serrated, grass-green, veiny, and hairy. The stipules of the stem-leaves very large, round, lobed, serrated, leafy. The flowers terminal, solitary, stalked, commonly small, bright yellow, erect. The calyx spreading, reflexed as the fruit advances. Achenia in an ovate head, numerous, downy, besides a few long coarse hairs about the summit, each tipped with a ripe purplish deflexed awn or tail, which is quite smooth, ending in a sharp small hook.

G. Canadense, Chocolate-Root, Blood-Root, is valued in Prince Edward's Island for its leaves and root, which are used as a mild tonic.

G. intermedium is found in damp woods in England. It has erect or nodding flowers; petals roundish, with a wedge-shaped claw; calyx of the fruit patent; carpophore 0; lower joint of the awn longer than the hairy upper joint; radical leaves interruptedly pinnate and lyrate; stem-leaves 3-lobed; stipules round, toothed; stem from 1 to 2 feet high. The flowers are larger than those of *G. urbanum*, less than *G. rivale*, yellow; calyx purplish. The upper joint of the awn is covered with long hairs, but with rather a long glabrous point.

(Lindley, *Flora Medica;* Babington, *Manual of British Botany*.)

GEYSERS. This name is applied to a series of intermittent hot-springs, situated in the south-western division of Iceland, where nearly one hundred of them are said to break out within a circle of two miles. These springs are evidently connected with the volcanic phenomena which so remarkably characterise the whole district of Iceland. A recent investigator of the eruptive phenomena of Iceland thus describes its more prominent physical features:—

"The surface of Iceland slopes gradually from the coast towards the centre, where the general level is about 2000 feet above the surface of the sea. On this, as a pedestal, are planted the Jökull, or Icy Mountains of the region, which extend both ways in a north-easterly direction. Along this chain the active volcanoes of the island are encountered, and in the same general direction the thermal springs occur, thus suggesting a common origin for them and the volcanoes. From the ridges and chasms which diverge from the mountains mighty masses of steam are observed to issue at intervals, hissing and roaring, and where the escape takes place at the mouth of a cavern, and the resonance of the cave lends its aid, the sound is like that of thunder. Lower down in the more porus strata we have smoking mud pools, where a repulsive blue-black aluminous paste is boiled, rising at times into huge bladders, which on bursting scatter their slimy spray to a height of 15 or 20 feet. From the base of the hills upwards extend the glaciers, and on their shoulders are placed the immense snow-fields which crown the summits. From the arches and fissures of the glaciers vast masses of water issue, falling at times in cascades over walls of ice, and spreading for miles and miles over the country before they find definite outlet. Extensive morasses are thus formed, which lend their comfortless monotony to the dismal scene already before the traveller's eye. Intercepted by the cracks and fissures of the land a portion of these waters is conducted to the hot rocks underneath; here, meeting with the volcanic gases which traverse these underground regions, both travel together, to issue at the first convenient opportunity either as an eruption of steam or as a boiling spring.

"The origin of the water which feeds the springs is here hinted at. That origin is atmospheric. The summits of the Jokull arrest and mix the clouds, and thus cause an extraordinary deposition of snow and rain. This snow and rain constitute the source from which the springs are fed. The nitrogen and ammonia which occur without exception in every spring, exactly as we find them in rain water, furnish the proof of this; for the known deportment of these substances preclude them from being regarded as real volcanic products."

The springs which feed the Geysers, and which are poured out from them again boiling hot, probably take their rise in Mount Hecla, the summit of which is not more than 30 miles from the Geyser district. It is here that the rushing water is sometimes heard in chasms beneath the surface, and it has more than once happened that after earthquakes some of the boiling fountains have increased or diminished in violence and volume, or entirely ceased, or that new ones have made their appearance.

The phenomena of the Geysers of Iceland have for a length of time arrested the attention of naturalists, and many explanations of them have been given. No one has however so successfully investigated the subject as Professor Bunsen, of Giessen. A summary of these views, with experimental illustrations, were presented to the Royal Institution by Professor Tyndall in June 1853. After referring to the general eruptive phenomena of Iceland he described the Great Geyser. "We have here," he says, "a tube 10 feet wide and 70 feet deep; it expands at its summit into a basin, which from north to south measures 52 feet across, and in the perpendicular direction 60 feet. The interior of the tube and basin is coated with a beautiful smooth plaster, so hard as to resist the blows of a hammer. The first question that presents itself is, how was this wonderful tube constructed? How was this perfect plaster laid on? A glance at the constitution of the geyser water will perhaps furnish the first surmise. In 1000 parts of the water the following constituents are found:—

Silica	0·5097
Carbonate of Soda	0·1939
Carbonate of Ammonia	0·0083
Sulphate of Soda	0·1070
Sulphate of Potash	0·0475
Sulphate of Magnesia	0·0042
Chloride of Sodium	0·2521
Sulphide of Sodium	0·0088
Carbonic acid	0·0557

"The lining of the tube is silica, evidently derived from the water; and hence the conjecture may arise that the water deposited the substance against the sides of the tube and basin. But the water deposits no sediment, even when cooled down to the freezing point. It may be bottled up and kept for years as clear as crystal, and without the slightest precipitate. A specimen brought from Iceland and analysed in this institution was found perfectly free from sediment. Further, an attempt to answer the question in this way would imply that we took it for granted that the shaft was made by some foreign agency, and that the spring merely lined it. A painting of the Geyser, the property of Sir Henry Holland—himself an eye-witness of these wonderful phenomena—was exhibited. The painting, from a sketch taken on the spot, might be relied on. We find here that the basin rests on the summit of a mound; this mound is about 40 feet in height, and a glance at it is sufficient to shew that it has been deposited by the geyser. But in building the mound the spring must also have formed the tube which perforates the mound; and thus we learn that the geyser is the architect of its own tube. If we place a quantity of the geyser water in an evaporating basin the following takes place:—In the centre the fluid deposits nothing, but at the edges where it is drawn up the sides of the basin by capillary attraction, and thus subjected to a quick evaporation, we find silica deposited; round the edge we find a ring of silica thus laid on, and not until the evaporation is continued for a considerable time do we find the slightest turbidity in the central portions of the water. This experiment is the microscopic representant, if the term be permitted, of nature's operations in Iceland. Imagine the case of a simple thermal spring whose waters trickle over its side down a gentle incline; the water thus exposed evaporates speedily, and silica is deposited. This deposit gradually elevates the side over which the water passes, until finally the latter has to choose another course; the same takes place here, the ground becomes elevated by the deposit as before, and the spring has to go forward—thus it is compelled to travel round and round, discharging its silica and deepening the shaft in which it dwells, until finally, in the course of centuries, the simple spring has produced that wonderful apparatus which has so long puzzled and astonished both the traveller and the philosopher.

"Before an eruption the water fills both the tube and basin, detonations are heard at intervals, and after the detonation a violent ebullition in the basin is observed; the column of water in the pipe appears to be lifted up, thus forming a conical eminence in the centre of the basin and causing the water to flow over its rim. The detonations are evidently due to the production of steam in the subterranean depths, which, rising into the cooler water of the tube, becomes condensed and produces explosions similar to those produced on a small scale when a flask of water is heated to boiling. Between the interval of two eruptions the temperature of the water in the tube towards the centre and bottom gradually increases. Bunsen succeeded in determining its temperature a few minutes before a great eruption took place; and these observations furnished to his clear intellect the key of the entire enigma. A little below the centre the water was within two degrees of its boiling point, that is, within two degrees of the point at which water boils under a pressure equal to that of an atmosphere, plus the pressure of the superincumbent column of water. The actual temperature at 30 feet above the bottom was 122° centigrade, its boiling point here is 124°. We have just alluded to the detonations and the lifting of the geyser column by the entrance of steam from beneath. These detonations and the accompanying elevation of the column are, as before stated, heard and observed at various intervals before an eruption. During these intervals the temperature of the water is gradually rising. Let us see what must take place when its temperature is near the boiling point. Imagine the section of water at 30 feet above the bottom to be raised six feet by the generation of a mass of vapour below. The liquid spreads out in the basin, overflows its rim, and thus the elevated section has six feet less of water pressure upon it; its boiling point under this diminished pressure is 121°; hence in its new position its actual temperature (122°) is a degree above the boiling point. This excess is at once applied to the generation of steam; the column is lifted higher, and its pressuro further lessened; more steam is developed underneath; and thus, after a few convulsive efforts, the water is ejected with immense velocity, and we have the geyser erpption in all its grandeur. By its contact with the atmosphere the water is cooled, falls back into the basin, sinks into the tube through which it gradually risos again, and finally fills the basin. The detonations are heard at intervals, and ebullitions observed; but not until the temperature of the water in the tube has once more nearly attained its boiling point is the lifting of the column able to produce an eruption.

"In the regularly-formed tube the water nowhere quite attains the boiling point. In the canala which feed the tnbe, the steam which causes the detonation and lifting of tho column must therefore be formed. These canals are in fact nothing more than the irregular continuation of the tube itself. The tube is therefore the sole and snfficient cause of the eruptions. Its sufficiency was experimentally ahown during the lecture. A tube of galvanised iron six feet long was surmounted by a basin; a fire was placed underneath and one near its centre to imitate the lateral heating of the geyser tube. At intervals of five or six minutes throughout the lecture eruptions took place; the water was discharged into the atmosphere, fell back into the basin, filled the tube, became heated again, and was discharged as before.

"Sir George Mackenzie, it is well known, was the first to introduce the idea of a subterranean cavern to account for the phenomena of the Geyser. His hypothesis met with general acceptance, and was even adopted undoubtingly by some of those who accompaued Bunsen to Iceland. It is unnecessary to introduce the solid objections which might be urged against this hypothesis, for the tube being proved sufficient, the hypothetical cavern disappears with the necessity which gave it birth.

"From the central portions of the geyser tube downwards, the water has stored up an amount of heat capable, when liberated, of exerting an immense mechanical force. By an easy calculation it might be shown that the heat thus stored up could generate, under ordinary atmospheric pressure, a column of steam having a section equal to that of the tube and a height of nearly 1300 yards. This enormous force is brought into action by the lifting of the column and the lessening of the pressure described above.

"A moment's reflection will suggest to us that there must be a limit to the operations of the Geyser. When the tube has reached such an altitude that the water in the depths below, owing to the increased pressure, cannot attain its boiling point, the eruptions of necessity cease. The spring however continues to deposit its silica and forms a 'laug,' or cistern. Some of these in Iceland are of a depth of 30 or 40 feet. Their beauty is indescribable; over the surface a light vapour curls, in the depths the water is of the purest azure, and tints with its own hue the fantastic incrustations on the cistern walls; while at the bottom is observed the mouth of the once mighty Geyser. There are in Iceland traces of vast, but now extinct, geyser operations. Mounds are observed whose shafts are filled with rubbish, the water having forced a way underneath and retired to other scenes of action. We have in fact the Geyser in its youth, manhood, old age, and death, here presented to us:—in its youth as a simple thermal spring, in its manhood as the eruptivo spring, in its old age as the tranquil laug, while its death is recorded by the ruined shaft and mound, which testify tho fact of its onco active existence.

"Next to the Great Geyser the Strokkur is the most famous eruptive spring of Iceland. The depth of its tube is 44 feet. It is not however cylindrical like that of the Geyser, but funnel-shaped. At the mouth it is 8 feet in diameter, but it diminishes gradually, until near the centre the diamcter is only 10 inches. By casting stoues and peat into the tube and thus stopping it, eruptions can be forced which in point of height often exceed those of the Great Geyser. Its action was illustrated experimentally in the lecturc, by stopping the galvanised iron tube before alluded to loosely with a cork. After some time the cork was forced up and the pent-up heat converting itself suddenly into steam, the water was ejected to a considerable height—thus demonstrating that in this case the tube aloue is the sufficient cause of the phenomenon." ('Proceedings of Royal Institution.')

The results of the researches of Professor Bunsen on the Geysers of Iceland seem to throw great and unexpected light on the phenomena of volcanoes. Sir Charles Lyell closes his account of Bunsen's researches with the following remarks:—

"In speculating therefore on the mechanism of an ordinary volcanic eruption, we may suppose that large subterranean cavities exist at the depth of some miles below the surface of the earth, in which melted lava accumulates, snd when water containing the usual mixture of air penetrates into these, the steam thus generated may press upon the lava and force it up the duct of a volcano, in the same manner as a column of water is driven up the pipe of a Geyser. In other cases we may suppose a continuous column of liquid lava, mixed with red-hot water (for water may exist in that state, as Professor Bunsen reminds us, under pressure), and this column may have a temperature regularly increasing downwards. A disturbance of equilibrium may first bring on an eruption near the surface, by the expansion and conversion into gas of entangled water and other constituents of what we call lava, so as to occasiou a diminution of pressure. More steam would then be liberated, carrying up with it jets of melted rock, which being hurled up into the air may fall in showers of ashes on the surrounding country, and at length, by the arrival of lava and water more and more heated at the orifice of the duct or the crater of the volcano, expansive power may be acquired sufficient to expel a massive current of lava. After the eruption has ceased a period of tranquillity succeeds, during which fresh accessions of heat are communicated from below, and additional masses of rock fused by degrees, while at the same time atmospheric or sea-water is descending from the surface. At length the conditions required for a new outburst are obtained, and another cycle of similar changes is renewed." ('Principles of Geology,' p. 558.)

GIANT, a man of great or unnatural stature. In the following article we shall mention those deviations from nature which sometimes occur in the proportions of the human form, both as regards the arrest or excess of development, and thus include the description of Dwarfs, or men who are unnaturally small, and beneath the usual size, as well as of Giants, who exceed the ordinary proportions of the human race. In considering this subject we will first allude to the question,—whether the size of man generally was ever different from what it is at the present time. Secondly, we will inquire if it is probable that races or nations of giants or pygmies ever existed. Lastly, we will state the ordinary proportions of the human frame, and enumerate a few examples of men who have much exceeded or have fallen far short of the common standard, and inquire whether these peculiarities of stature can be accounted for in any satisfactory manner.

It is a very common opinion, that in the earlier ages of the world men in general possessed superior physical properties, and were of a greater size than they are at present; and this notion of diminished stature and strength seems to have been just as prevalent in ancient times as at present. Pliny observes of the human height (vii. 16), that "the whole race of mankind is daily becoming smaller;" a most alarming prospect if it had been true. Homer more than once makes a very disparaging comparison between his own degenerate contemporaries and the heroes of the Trojan war. But all the facts and circumstances which can be brought forward on this subject tend to convince us that the human form has not degenerated, and that men of the present age are of the same stature as in the beginning of the world. In the first place, though we read both in sacred and profane history of giants, yet they were at the time when they lived esteemcd as wonders, and far above the ordinary proportions of mankind. All the remains of the human body (as bones, and particularly the teeth), which have been found unchanged in the most ancient urns and burial-places, demonstrate this point clearly. The oldest coffin in the world is that found in the great pyramid of Egypt, and Mr. Greaves observes that this sarcophagus hardly exceeds the size of our ordinary coffins, being scarcely six feet and a half loug. From looking also at the height of mummies which have been brought to this country, we must conclude that the people who inhabited Egypt two or three thousand years ago were not superior in size to the present iuhabitants of that country. Lastly, all the facts which we cau collect from ancient works of art, from armour, as helmcts and breastplates, or from buildings designed for the abode and accommodation of meu, concur in strengthening the proofs against any decay in uature. That man has not degenerated in stature in consequence of the effects of civilisation is clear; because the inhabitants of savage countries, as the natives of America, Africa, Australia, or the South Sea Islands, do not exceed us in size. It has been supposed that before the Delugo men might have been of a larger form than they are at present, as they are said to have lived to a much greater age; but this is a mere assumption, unsupported by any evidence whatever.

When investigating tho subject, whether any peculiar races of meu have ever existod who have greatly varied iu size from tho ordinary proportions of our form, we need not allude to the fabulous stories of the giants and pygmies of antiquity, the former of whom are said to have made war against Jupiter, and the latter to have been not more than a foot high, and to have carried on war against the cranes which used to come and plunder them. Mention is made of giants in several places in Scripture, before the Flood, in the sixth chapter of Genesis, and more plainly after it (Numbers, xiii.); but, as Dr. Derham observes, the ancients vary as to the signification of the Hebrew word 'nephilim' in Genesis. Some translate it by a word signifying 'violent men,' and think that instead of giants in stature, monsters of rapine and wickedness were intended to be represented; and Dr. Johnson says that the idea of a giant is always associated with something fierce, brutal, and wicked. With regard to the giants in Numbers, who are more particularly mentioned, it is probable that the fears of the spies magnified their dimensions. Races of giants are also alluded to by the Greek and Roman historians. The Germans are particularly noticed by Cæsar ('De Bel. Gall.,' lib. i.), and by Tacitus ('De Morib. German.,' c. 4), as being of large size. We have no data for determining their exact stature, but there is no proof that it exceeded that of the tallest of the present German races, many of whom, as the inhabitants of Saxony and the Tyrol, are very large men. The notion of the existence of giants in former times, has in many instances been founded on the discovery of the bones of different large animals belonging to extinct species, which have been ascribed to human subjects of immoderate stature. (See the story in Herodotus, i. 68.) The bones of an elephant have even been figured and described by Buffon as remains of human giants, in the supplement to his classical work (tom. v.). The extravagance of such suppositions has been completely exposed by the accuracy of modern investigation.

Descending to more modern times, the people who have excited the most curiosity and given rise to the most conflicting statements are the Patagonians. The first navigators by whom they were observed represented them as being of colossal stature; but though more recent and accurate accounts describe them as being a very tall race of men, yet the highest does not much exceed 7 feet. Captain Wallis measured several of them carefully, and found that the stature of the greater part was from 5 feet 10 inches to 6 feet. The height of the Patagonians was also measured with great accuracy by the Spanish officers in 1785 and 1786: they found the common height to be from 6½ to 7 feet, and the highest was 7 feet 1¼ inch.

It was once supposed that a nation of white dwarfs existed in the interior of Madagascar, called Quimos or Kimos, with very long arms, but the report is now believed to be perfectly fabulous, and the only fact adduced in support of it was that the Count de Modave, the governor of the French settlement at Fort Dauphin, purchased a female slave of light colour, about 3½ feet high, with long arms reaching to her knees. Blumenbach thinks that this was merely a mal-formed individual. From these and similar observations we may conclude that there is no truth in the existence of giants or dwarfs, except in peculiar individual instances; at any rate, as Dr. Pritchard observes ('History of Mankind'), "every variety of stature which has been found to occur, as the general character of a whole race, is frequently surpassed by individual examples among the inhabitants of the same country."

There is no fixed law by which the human stature can invariably be determined, though there is an average standard from which the deviations either way are not very considerable. The human race varies mostly in height from 4½ feet to a little more than 6 feet, though men are occasionally met with of a much greater stature. Taking away the disposition to deal in the marvellous, we may probably assert that no man ever existed of the height of more than 8 or 9 feet. This may be supposed from what we see at present, and from the deviations which occur in the ordinary course of nature in animals. A skeleton was dug up some years ago on the site of a Roman camp near St. Albans, beside an urn inscribed 'Marcus Antoninus.' Mr. Cheselden, who has described it in the 'Philosophical Transactions' (No. 333), judged that it was 8 feet in height. Goliath, Og (king of Basan), Maximinus the emperor, and others mentioned in sacred and profane history, were also probably very tall men, whose height has been magnified, but who were no bigger than some now occasionally met with. There are many authentic instances of men who have much exceeded the ordinary height, which have occurred in our own times: one of the King of Prussia's gigantic guards, a Swede, measured 8½ feet; and a yeoman of the Duke John Frederick, at Brunswick-Hanover, was of the same height. (Haller, 'Element. Phy.,' lib. xxx. sec. 1. Several Irishmen, measuring from 7 to 8 feet and upwards, have been exhibited in this country; the most celebrated, whose skeleton is in the museum of the College of Surgeons in London, was Charles Byrne, who went by the name of O'Brien: he died at the age of 22, in 1783, and measured 8 feet 4 inches. The skeleton is 8 feet in height. Many examples of dwarfs might also be mentioned. Buffon says that Bebe, the dwarf of Stanislaus, king of Poland, was 23 inches (French) high, and well-proportioned: he died at 23. But of numerous other instances on record most seem to have been ricketty and diseased individuals. Thus, in the skeleton in the museum of the College of Surgeons, of Madlle. Crachami, the Sicilian dwarf, who died at the age of 10 years, and which is only 20 inches in height, the bones appear to have undergone hardly any change after birth. There seems to have been a complete arrest of development, the epiphyses of the bones remaining unossified. One of the most perfect specimens of a dwarf was the individual exhibited in London under the name of General Tom Thumb. He was 28 inches in height, and his head and limbs were remarkably well proportioned. Two dwarfs from South America were exhibited in London in 1853, and called Aztecs. Their heads were small in proportion to their bodies. They exhibited the deficiency of intellect indicated by the small development of their brains.

We may remark that the ordinary size of man is particularly well adapted to his wants and uses; and we generally observe that those individuals who deviate greatly from the common standard, either one way or the other, are neither well-proportioned nor healthy. The head in giants is commonly too small for the rest of the body, and in dwarfs too large.

Both giants and dwarfs have frequently offspring of similar stature to their own, so that a race of men might possibly arise of extraordinary smallness or gigantic size. Of the propagation of giants we have an experimental proof in a fact related by Dr. J. R. Forster ('Observations on a Voyage Round the World'). It is well known that the king of Prussia had a corps of gigantic guards, consisting of the tallest men who could be drawn together from all quarters. A regiment of these huge men was stationed during fifty years at Potsdam. "A great number of the present inhabitants of that place," says Forster, "are of very high stature, which is more especially striking in the numerous gigantic figures of women. This certainly is owing to the connexions and intermarriages of those tall men with the females of that town." Dr. Pritchard is of opinion that peculiarities of stature may in some measure be owing to peculiarities of climate. In his 'History of Mankind' (vol. ii.), he observes, that "there are many nations of very considerable stature in South America. The Patagonians are the most remarkable example, but nearly all the nations of this great country, though distinct from each other in language, manners, and descent, are taller and stouter than the average standard of the human species. . . In Ireland men of uncommon stature are often seen, and even a gigantic form and stature occur there much more frequently than in this island: yet all the British Isles derived their stock of inhabitants from the same sources. We can hardly avoid the conclusion that there must be some peculiarity in Ireland which gives rise to these phenomena." Again: "The tall, lank, gaunt, and otherwise remarkable figures of the Virginians and men of Carolina are strikingly different from those of the short, plump, round-faced farmers in England, who are of the same race." Lawrence ('Lectures on Man') thinks that the source of the deviations from the ordinary stature in man is entirely in the breed, and that they are quite independent of external influences. In endeavouring to account for the diversities of stature which occur we must make an observation which is equally applicable to differences of colour, features, and other particulars, in which individuals and particular races differ from each other, namely, that the law of resemblance between parents and offspring which preserves species, and maintains uniformity in the living part of creation, suffers occasional and rare exceptions; but that under certain circumstances an offspring is produced with new properties different from those of the progenitors.

GIANTS' CAUSEWAY, a remarkable columnar basaltic formation on the northern coast of the county of Antrim, in Ireland, situated about midway between the towns of Ballycastle and Coleraine.

The trap district with which this formation is connected occupies almost the whole of the county of Antrim, and a considerable portion of the eastern part of Londonderry, comprehending an area of about 800 square miles on both sides of the valley of the Bann. The surface rises gradually from the channel of this river till it attains a considerable elevation on each side, when it breaks down in precipitous escarpments, sloping abruptly to the primitive district of Londonderry on the west, and overhanging the coast on the east and north in a series of striking elevations commencing near Belfast, and terminating west of the embouchure of the Bann. Throughout this area the basalt is found capping all the eminences, and constituting the general super-stratum in beds of an average thickness of about 500 feet. Beneath the basalt occurs a series of secondary formations peculiar to this area, which has led to the supposition that they may have been elsewhere removed by some denuding force, "to which, in this quarter alone, an effectual resistance was opposed by the firm and massive super-stratum of basalt which covered and protected them." (Rev. W. Conybeare, in 'Trans. Geological Soc.,' vol. iii. p. 127.)

These formations, which are similar to those underlaid by the coal-measures of the south and east of England, consist, in descending order, of thick beds of indurated chalk, the white limestone of Antrim, succeeded (unless where the series is broken, as it frequently is, by the superior stratum extending beyond the outgoings of the inferior, as at Fair-head, where the basalt rests immediately upon the coal-measures), by mulatto or green sandstone reposing on blue argillaceous limestone, which again rests on the red-sandstone of the coal-formation, which appears to underlie the greater part of the basaltic tract.

The mass of basalt is considerably thicker towards the northern extremity of the area, and it is here chiefly that the series of columnar formations occur. There are three distinct beds of such formations, the uppermost of which is perhaps traceable in the cliffs of the Cave-Hill over Belfast, and is distinctly observable at Fairhead, on the north-eastern extremity of the coast, where the mural precipice of greenstone is articulated into columns of enormous dimensions but rude structure, some of them measuring 250 feet in length by 6 feet on the side. The same formation appears occasionally to recur along the verge of the precipice which trends westward hence to Dunseverick, at a short distance from which the two lower beds emerge from the sea, and, rising along the escarpment of the rock, form colonnades of the most striking appearance for a distance of nearly three miles, when the upper one is lost in the surrounding masses of basalt, while the lower stratum sinks again under water, its denuded extremity forming that particular group of columns known as the Giants' Causeway.

A section of the cliff at Bengore-Head, immediately adjoining the Causeway, gives the following arrangement:—

	Feet.
1. Basalt, rudely columnar	60
2. Red Ochre, or Bole	9
3. Basalt, irregularly prismatic	60
4. Columnar Basalt	7
5. Intermediate, between Bole and Basalt	8
6. Coarsely Columnar Basalt	10
7. Columnar Basalt, the upper range of pillars at Bengore-Head	54
8. Irregular Prismatic Basalt. In this bed the wacke and wood coal of Port Noffer are situated	54
9. Columnar Basalt, the stratum which forms the Causeway by its intersection with the plane of the sea	44
10. Bole, or Red Ochre	22
11, 12, 13. Tabular Basalt, divided by seams of Bole	80
14, 15, 16. Tabular Basalt, occasionally containing Zeolite	80
	488

It is observable that the dimensions of the columns diminish and the perfection of their structure increases as the strata descend. Thus the most perfect arrangement is found in the lowest stratum, of which arrangement the Causeway affords the most perfect specimen. The upper part of the stratum being here denuded for a distance of about 300 yards, exhibits an irregular pavement formed of the tops of polygonal columns, so closely arranged that the blade of a knife can with difficulty be inserted in the interstices. The columns are chiefly hexagonal, but polygons of five, seven, and eight sides are of frequent occurrence; and there is one instance of a triangular prism. These columns are divided into joints of unequal length; each joint is formed by the adjacent extremities being relatively convex and concave, an arrangement which is further secured by the overlapping of the external angles. These convexities and concavities are segments of spheres, the base of each of which occupies a circle inscribed in the polygon of the pillar; the intervals intercepted between the peripheries of these circles and the sides of the polygon are all in the plane perpendicular to the axis of the column. The stone is the most compact and homogeneous variety of basalt, and is more or less sonorous when struck with a hard substance. The entire mass of these columns, of which about thirty feet are exposed above the surrounding shingle at the highest point of their denudation, bears a strong resemblance to an artificial mole projecting from the base of the cliff into the sea.

It is probable that the columnar beds of which the exposed edges present these remarkable appearances along the coast underlie the capping of tabular basalt to a considerable distance inland, as columnar façades break out on the seaward slope of the entire line of elevations extending from Ballycastle to Bushmills, and indications of a columnar tendency have been observed in beds of tabular basalt as far inland as Glen Rovel, near Cushindall, and at the Cave-Hill, near Belfast. Along the coast at Ushethaven, Roanscarave, and Thivigh, are several smaller causeways nearly as perfect as the one described. The columnar strata of the islands of Rathlin and Staffa indicate the extent of the same formation northward and eastward.

The vicinity of the Giants' Causeway affords numerous appearances confirmatory of the opinion that the basalt when superinduced over the secondary strata was in a state of fusion from heat: such are the conversion of old red-sandstone into hornstone, the conversion of clay-slate into flinty-slate, the conversion of coal into cinders, and in numerous instances the conversion of chalk into granular marble, all arising from the contact of trap dykes with the altered strata. At Kenbaan, near Ballintoy, the basalt is found inclosing detached masses of chalk, as well interspersed through trap dykes as in the mass of the formation. Similar instances occur near the Cave-Hill.

Although this is the most important trap district in Ireland, yet basaltic formations are not altogether peculiar to it, columnar façades having been observed in the county of Limerick. [BASALT.]

(*Philosophical Transactions; Transactions of the Geological Society*, vol. iii.; *Guide to the Giants' Causeway*, Dublin.)

GIBBON. [HYLOBATES.]

GIBBSITE, a Mineral consisting of a hydrate of alumina. It occurs in small stalactitic shapes, or mammillary, and incrusting. The colour is grayish or greenish-white. The surface is smooth but nearly dull. Structure sometimes nearly fibrous. Its hardness is 3 to 3·5. Specific gravity 2·3 to 2·4. It occurs in a bed of iron ore at Richmond in the United States of America. This mineral results from the decomposition of felspar, and consists of little else besides water and alumina.

GIESECKITE, a form of *Elæolite* from Greenland. [ELÆOLITE.]

GIGANTHOLITE, a Mineral which occurs crystallised in six- and twelve-sided prisms. Its cleavage is parallel to the six sides of the prism. Colour greenish to dark steel-gray. Lustre between vitreous and waxy. Hardness about 3·5. Specific gravity 2·862 to 2·878. It is found near Temmela in Finland. The following is its analysis by Wachtmeister:—

Silica	46·27
Alumina	25·10
Peroxide of Iron	15·60
Magnesia	3·80
Protoxide of Manganese	0·89
Potash	2·70
Soda	1·20
Fluorine, a trace	
Water with Ammonia	6·00
	——101·56

GILBERTITE, a Mineral occurring in plates lying irregularly together. Its colour is white with a shade of yellow. Hardness 2·75. Lustre silky. Translucent. Specific gravity 2·648. It is found near St. Austell, Cornwall. The following is its analysis by Lehunt:—

Silica	45·155
Alumina	40·110
Lime	4·170
Magnesia	1.900
Protoxide of Iron	2·430
Water	4·250
	——98·015

GILBERTSOCRINUS, a genus of fossil *Echinida*, from the Mountain Limestone. (Phillips.)

GILL-COVERS. [FISH.]

GILLENIA, a genus of Plants belonging to the natural order *Rosaceæ*, and the sub-order *Spireæ*. It has a tubularly campanulate 5-cleft calyx, 5 linear lanceolate petals, 10-20 stamens, very short, inclosed in the tube, 5 carpels almost united into a five-celled capsule, and 2 seeds in each cell. There are only two species of this genus.

G. trifoliata has several stems from the same root, a foot or two in height, alternate trifoliate leaves, the flowers, which are few in number, forming a sort of panicle. The calyx sub-campanulate, or tubular, with the lower half narrowest, the border divided into 5 reflexed acute teeth. Petals 5, the two upper ones separated from the three lower ones, white with a reddish tinge on the edge, lanceolate, unguiculate, contracted, and approximated at the base. The stamens about 20, in a double series within the calyx. Capsules 5, diverging, oblong, acuminate, 2-valved, 1- or 2-seeded. It is a native of North America in shady places, from Florida to Canada. The root is emetic, and possesses properties similar to those of ipecacuanha. It must however be administered in larger doses, and is not so certain in its effects. Some authors attribute a tonic power to this plant when taken in small doses.

G. stipulacea is distinguished by its foliaceous ovate deeply-cut stipules. It grows in humid woods and damp places from Tennessee to Kentucky, in North America. The medicinal properties of this species are the same as those of *G. trifoliata*.

The species of *Gillenia* are elegant and hardy plants, and are therefore worthy of cultivation. They grow best in a peat soil, and may be readily propagated by dividing at the roots early in the spring.

(Don, *Dichlamydeous Plants*; Lindley, *Flora Medica*.)

GILLIESIA'CEÆ, *Gillesiads*, a very singular natural order of Endogens, with the habit of the Scilleous division of *Liliaceæ*, but with extremely remarkable flowers. In the first place there are several bracts at the base of each flower, resembling a calyx, and in reality constituting an involucre; and secondly the calyx is either an urceolate 6-toothed body, or a single lobe resembling a labellum. Of the two known genera, *Gillesia* and *Miersia*, one has six perfect stamens, the other has only three perfect and the remainder sterile and nearly obliterated. They are natives of Chili. ('Botanical Register,' folio 992.)

GILLS. [FISH.]

GILLYFLOWERS, the common name of the Garden Stock, *Matthiola incana*. [MATTHIOLA.]

GILT-HEAD. [CHRYSOPHRYS; CRENILABRUS.]

GINGER. [ZINGIBER.]

GINSENG, a root found in China, to which extraordinary properties have been ascribed: it is not only considered a universal remedy for all maladies, but is spoken of in the highest terms as a specific in particular circumstances. Volumes have been written in Chinese upon the supposed virtues of this root. It is affirmed that it wards off fatigue, invigorates the enfeebled frame, restores the exhausted animal powers, makes old people young, and so on. The weight in gold has been given by the Chinese for this root, which we are told grows only in the most remote and inaccessible parts of Chinese Tartary, where its collection is attended by dangers sufficient to appal the stoutest man. Nevertheless botanists believe the Ginseng to be nothing more than a plant called *Panax quinquefolium*, also found in North America, where no such qualities as those spoken of by the Chinese are recognised.

GIRAFFA (Camelopard of Pennant and authors), a genus of Ruminants, with persistent horns common to both sexes, comprising the tallest of the known quadrupeds. Dr. J. E. Gray makes this genus the type of the tribe *Giraffina*. Horns covered with a hairy skin, with a tuft of hair at the tip. He gives the following synonyms:—

Camelopardina, Gray, 'Ann. Phil.' 1825; 'Cat. Mamm. B. M.' xxvi.
Camelopardalis, Cuv. 'Tab. Elem.' 1798.
Giraffidæ, Gray, 'L. M. Rep.' xv. 307, 1821; H. Smith, Griffith, 'A. K.' v.; J. Brookes, 'Cat. Mus.' 63, 1828.
Derexa, Illiger, 'Prod.' 104, 1811.
Plenicornia, b, Latr. 'Fam. Nat.' 1821.
Camelopardalidæ, Selys Longchamps, 1842.
Elaphiens, part., 'Pomet.' l. c. 184.
Ruminalia stereoceria, part., 'Rafin. Anal. Nat.' 56, 1815.
Ruminantia B. Pygnocerate, part., Bronn, 'Index Palæont.' ii. 709.
Cameli, β, Wagler, 'N. Syst. Amph.' 4—31, 1830.
Cervidæ, part., Ogilby, 'P. Z. S.' 134, 1836.
Cervicornia, §, Sundevall, 'Pecora,' 52.
Unguligrada, part., Sundevall, 'Pecora,' 52.
Ossicornia, Rüppell, 'Verz. Senck. Samml.' 183, 1845.
Camelopardalina, Sundevall, 'Pecora,' 52.
Camelopardineæ, Lesson, 'N. Tab. R. A.' 168, 1842.
Les Girafes, F. Cuvier, 'D. Sci. Nat.' lix. 513.

Giraffa has the following characters:—Lip not grooved, entirely covered with hair, much produced before the nostril; tongue very extensile; neck very long; body short; hinder legs short; false hoof none; tail elongate, with a tuft of thick hair at the end.

G. Camelopardalis, the Giraffe or Camel-Leopard, is the only species. It is the *Cervus Camelopardalis*, Linn.; *C. Capensis*, Geoff., Ogilby; *Camelopardalis Giraffa, a*, Sundevall; *Giraffa Camelopardalis*, Brisson; *Camelopardalis Girafa*, Gmelin.

There is a pale variety, which has the following synonyms:—*Camelopardalis Girafa, β. Æthiopica*, Sundevall; *Camelopardalis Sennaarensis*, Geoff.; *Camelopardalis Æthiopicus*, Ogilby; *Camelopardalis*, Plin.; *Camelo-pardalus*, Jonst.; *Camelus Indicus*, Jonst.; Gyraffe, Belon; *Tragus Giraffa*, Klein; Camelopard, Penn.; Kamel paard, Vosmaer; Giraffe—Thevet, Buffon, Levaill., Shaw, Lichtenst.; Giraffe, or Cameleopard, Harris.

The structure and history of this extraordinary animal have a high interest for the naturalist. We shall first speak of the anatomy of its bones.

The skeleton of a Giraffe arrests the attention of the observer at once:—the head lifted on high upon the extremely elongated neck, the high withers, and the slender length of limb, taken together, contrast strangely with the bony fabrics of the other quadrupeds. A man who looks up at such a skeleton for the first time, and without previous knowledge of its structure, must be struck at finding that the towering neck consists of exactly the same number of bones that form his own. The skull is light and thin. The horns are considered by Dr. Rüppell (who during his travels in Northern Africa obtained in Nubia and Kordofan three specimens, two males and one female) as constituting the principal generic character, they being formed by distinct bones, united to the frontal and parietal bones by a very obvious suture, and exhibiting throughout the same structure as the other bones. In both sexes, he observes, one of these abnormal bones is situated on each branch of the coronal suture, and the male possesses an additional one, placed more anteriorly, and occupying the middle of the frontal suture. The existence of this third appendage is considered to furnish a complete refutation of Camper's theory with regard to the unicorn, namely, that such an occurrence is contrary to nature, and to prove at least the possibility of the existence of such an animal. This appendage is conspicuous in the plate containing the crania ('Atlas zu der Reise im Nördlichen Afrika,' von Eduard Rüppell; pl. 9, fig. *a, a*); and, as it is there represented, rises abruptly from the os frontis with all the appearance of a third horn. Cuvier, in his last edition of the 'Règne Animal' (1829), follows Dr. Rüppell; and, speaking of the horns, says their bony core (noyau osseux) is articulated in youth by a suture on the frontal bone. In the middle of the chanfrein is a tubercle, or a third horn, larger and much shorter, but equally articulated by suture.

The well-known accuracy of Dr. Rüppell demands every degree of respect; and if the figure alluded to be a correct representation of the ordinary state of the adult Nubian male Giraffe, and not an accidental deformity, the third horn would form a good ground for specific distinction. There are skulls of the Cape Giraffe, both male and female, in the museum of the College of Surgeons, and that of the male, which is an adult with the persistent teeth, has no such horn; but there is a considerable gradually-rising protuberance, which is more strongly developed than the same part in the female cranium. In all the crania which we have seen, and in all the living specimens, the females possess this protuberance as well as the males, though not in so high a degree of development; and the true horns, at least the bony cores, are much larger in the male than in the female. It may be said that the living and dead specimens which were at first received from North Africa were comparatively young, though some of them were not so very young. In the giraffes in the Garden of the Zoological Society at the Regent's Park the protuberance will be seen, though that of the female is not quite so highly marked perhaps as those of the males. In a paper read before the Zoological Society of London, Professor Owen has shown that this middle protuberance arising from the head is not a true horn articulated by a suture, but merely a thickening of the os frontis. This position Professor Owen is enabled to lay down from the section of the skull of a male (Northorn) Giraffe, and from the examination of various crania of both Nubian and Cape (male and female) old and young giraffes. There appears to be no evidence to lead to the conclusion that there is anything at any time in this part of the structure naturally that

Skull of the male Giraffe, from Rüppell's figure.

can be considered more than a mere frontal protuberance occasioned by the thickening of the bone—a protuberance which will not separate upon maceration as the two horns will, in the young animal at least. The lightness of the cranium is owing in great measure to the sinuses, which are minutely described by Professor Owen in his paper; these run along the whole upper part of the cranium, and the occiput is raised by their extension. He shows that a principal object of these sinuses is to increase the surface of the attachment of the ligament supporting the head, and draws attention to the remarkable vertical extension of the condyles of the occiput—a structure which enables the animal to tilt its head back, and gracefully and easily to raise it till it is on a line with the neck. The reader will find the section of the head above alluded to in the museum of the Royal College of Surgeons. In the same museum he will find entire crania of the Cape Giraffe (male and female), with other detached bony parts, and a perfect skeleton of the Nubian Giraffe, though it is that of a comparatively young animal. The position and appearance of the elastic cartilages on the posterior edges of the scapulæ are here exhibited, a beautiful provision for the easy springy carriage of the body, which is principally suspended from the muscles there attached, and slung as it were between those points and the sternal and lumbar regions. In the British Museum and the museums of the Geological Society and College of Surgeons, London, are specimens of the skeletons of this animal.

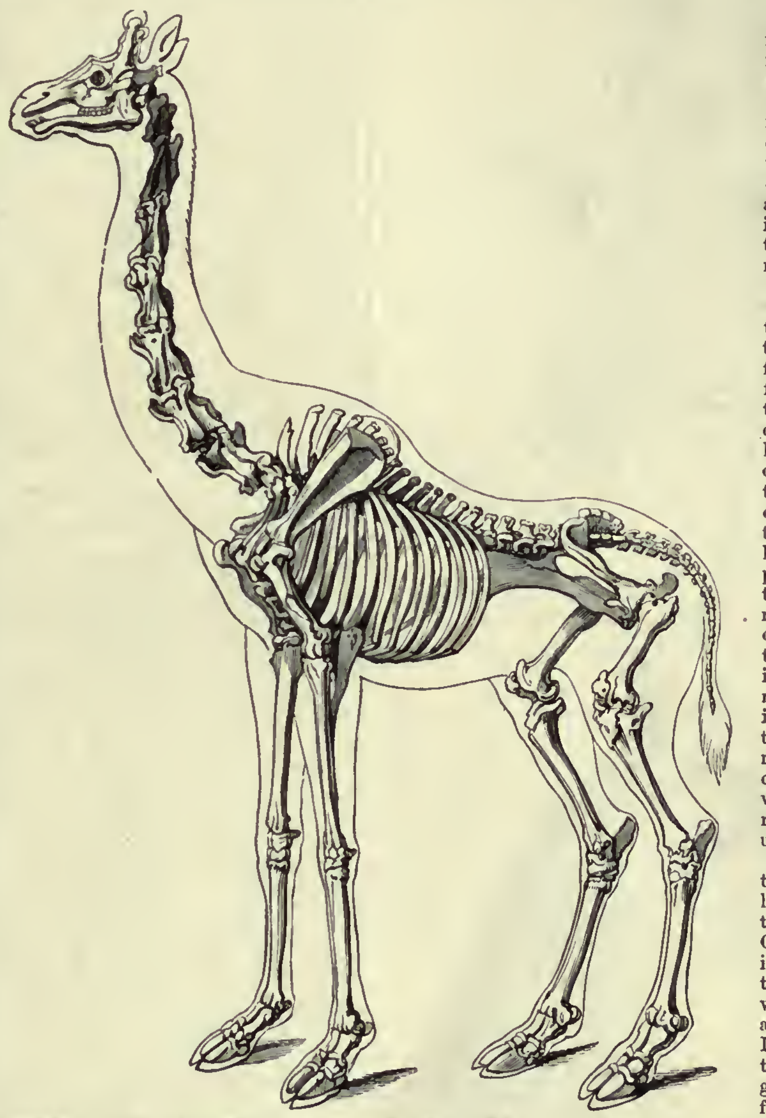
Professor Owen found the ligamentum nuchæ immense, consisting of two bilateral moieties; it commences at the sacrum, gains fresh accessions from each dorsal vetebra, the spines of which are remarkably elongated for that purpose, is inserted into all the cervical vertebræ, with the exception of the atlas, and attached to the extended surfaces of the occipital region of the skull produced by the organisation above alluded to. Before we proceed to notice the softer parts we must refer to the dentition, which offers the same formula as that characteristic of the deer, goat, antelope, sheep, and ox, namely,

$$\text{Incisors, } \frac{0}{8}; \text{ canines, } \frac{0}{0}; \text{ molars, } \frac{6-6}{6-6} = 32.$$

In the 'Nova Acta Physico-medica Academiæ Cæsareæ Leopoldino-Carolinæ Naturæ Curiosorum,' tom. xii., part 1, is a paper by Dr. D'Alton on the teeth of the Giraffe, written, it would seem, principally with a view to correct the notion apparently entertained by Dr. Bojanus in a preceding paper in the same part, not only that the dentition of the *Merycotherium* has certain points indicatory of that animal being intermediate between the camels and the sheep, "camelinum inter et ovillum genus," but that it might possibly be the Giraffe. Dr. D'Alton figures the teeth of the latter, and shows, by a comparison with those of the *Merycotherium*, their discrepancy both in size and structure from those of the fossil animal.

The tongue of the Giraffe requires particular notice. Sir Everard Home remarks, that besides being the organ of taste, it has many properties of the proboscis of the elephant, one being an elongation of the organ of smell, the other of taste. The proboscis is incapable of elongation, he observes, beyond one inch in extent, in consequence of its cartilaginous tubes; while the tongue may be extended to 17 inches after death, and can in the living body lie so diminished in size as to be inclosed within the animal's mouth.

Some mechanism, he remarks, must exist by which this elongation may be performed, as in the tongue of the rein-deer; but he states that a post-mortem examination would be necessary to decide this. He notices the organ as being very smooth; that is, it is smooth when the papillæ are not raised, as they can be at pleasure, but rougher when they are, and slightly adhesive; it is spotted, but the spots are not raised, and there is a black rete mucosum, to prevent, as he thinks, the surface from being blistered by the exposure to the sun. "In the absence of an opportunity," continues Sir Everard, "of examining the internal structure of the Xariffa's tongue after death, I was led to the opinion that the change of size is effected by the organ containing a reservoir, out of the course of the circulation, which can be filled with blood at the will of the animal, so as to give it rigidity, and enable it to extend itself for the performance of the different actions in which it is employed with the smallest possible degree of muscular exertion. It occurred to me at the same time, that whatever construction may be the means by which the Xariffa's tongue is able to apply itself to such various purposes, whether that which appeared to me probable, or any other, something similar would be met with in other animals, particularly in the tongue of the deer, which, after death, readily admits of being drawn out to the extent of 8 inches, although when immersed in rectified spirits it contracts to 5 inches. For the purpose of such an examination, a deer's tongue, recently after the animal's death, was injected with minute red injection, so as to distend the arteries and show the course of the circulation in them to the greatest advantage. This tongue was afterwards divided longitudinally in a perpendicular direction, also in a horizontal one, to show the muscles of which it is composed, as well as the other parts that it contained." From this examination, the structure of the tongue of quadrupeds in general is described by Sir Everard as being longitudinally divided into two equal portions by a middle line; the muscular structure occupies the whole of the interior substance, receiving a large supply of nerves and bloodvessels from a lateral nerve and artery that pass along the outer edge; these are imbedded in a very loose cellular tissue, the texture of which admits of the bloodvessels being distended to a very great degree, so as to enlarge the volume of the tongue; and beyond this tissue, surrounding and forming a case for the whole of the upper and lateral part of the organ, is a strong very elastic covering of some thickness, which yields when the muscles and the trunks of the arteries are distended with blood, so as to give both extent and rigidity to the organ, and admit of the different actions in which it is employed. Sir Everard then adds, that there can be no doubt of the structure of the Xariffa's tongue being the same; its actions depending upon the combined powers of muscular contraction and elasticity; its increase and diminution of size arising from the bloodvessels being at one time loaded with blood and at another empty.



Skeleton of Giraffe; the curved outline from the posterior edge of the scapula shows the position of the elastic cartilage above alluded to.

The chief modification in the muscles of the tongue is in those destined to retract it. Professor Owen, in a note to his edition of 'Hunter's Animal Œconomy' (8vo., London, 1837), says, "A most beautiful and forcible example of the use of tendon in limiting the length of a muscle to the extent of motion required to be produced in the part to be moved, occurs in the sterno-thyroidei of the Giraffe. Had these muscles been continued fleshy as usual from their origin, through the whole length of the neck to their insertion, it is obvious that a great proportion of the muscular fibres would have been useless, because such a condition of the muscle would have been equal to have drawn down the larynx and os hyoides more than one-third of the extent of the neck, which is neither required nor permitted by the mechanical attachments of the parts. The sterno-thyroidei therefore proceed from the head of the sternum blended together in one fleshy fasciculus for about 9 inches, and end in a tendon which is continued for 6 inches; this then divides, and the muscles proceed again fleshy for about 16 inches, when a second tendon intervenes in each between the preceding and the next fleshy portion, which is finally inserted into the thyroid cartilage, and by a continued fascia into the os hyoides: thus the quantity of contractile fibre is proportioned to the required extent of motion by intervening tendons; the sterno-hyoidei being wanting, or their place supplied by the sterno-thyroidei, as in some other ruminants. The analogue of the omo-hyoideus is in the same animal adjusted to its office by a different and more simple modification; its origin is removed from the shoulder-blade to the nearest point (the third cervical vertebra), from which it could act with the requisite force and extent upon the os hyoides."

Sir Everard Home fancied that the Giraffe on which he made his observations, the individual belonging to George IV., preferred licking the hand of a lady to that of a man. Mr. Davis, who saw a great deal of the animal, never observed this. It may be easily believed that the animal distinguished the fair hand from which it received gifts and attention; but certainly the giraffes in the Zoological Garden at the Regent's Park exhibit no such preference. They appear to use their tongues generally as organs of examination, and the power of prehension is so great that we have seen the tongue, when extended to the utmost, grasp an ordinary lump of sugar, of which the animals seem very fond, and convey it into the mouth. We have also observed the giraffes retrovert the tongue for the purpose of cleaning the nostrils, an office which its flexibility enables it to perform in the most perfect manner. The utility of such a power of prehension and extension to an animal whose principal food consists of the leaves and slender twigs of trees is manifest. Mr. Davis says that the tongue can be so tapered as to enter the ring of a very small key.

With regard to the stomach and digestive organs generally, the Giraffe, it is true, wants the receptacle for water which the camel and dromedary possess. There are no water-cells belonging to the rumen as there are in *Camelidæ;* and this part of the structure is, as Professor Owen points out, fashioned according to the horned ruminant type. But he also shows that the reticulum is not, as stated by Sir Everard Home, "destitute of the cellular structure met with in other ruminants," but that it has cells, though very shallow ones, as in the rein-deer. Professor Owen further states that the coils of the colon in the Giraffe are spiral, as they are in the deer and in the antelopes; and that like them it has a simple cæcum, which is 2 feet 2 inches in length. The first giraffe (female) dissected by Professor Owen had a double gall-bladder, each bladder of the usual size: this is preserved in spirit in the museum of the College. The other two giraffes (males) were without a trace of gall-bladder. He believes therefore that absence of the gall-bladder, as in the deer (the antelopes have it), is the rule.

Head of Giraffe (Nubian) with the tongue elongated.

Head of Giraffe (profile), showing the frontal protuberance and the mane. (Nubian.)

The kidneys in the giraffes examined by Professor Owen were not lobulated as in the ox, but simple, as in the deer and antelopes.

Professor Owen found the male organs to agree with the horned ruminant type; that is, the prostate is divided, not single as in the camel. There is a peculiarity in the termination of the urethra; for it is continued as a membranous canal one inch and a half beyond the extremity of the glans, adhering to the prepuce. The female organs differ also from those of the camels, and agree with those of the true ruminants, exhibiting processes for the cotyledons in the interior of the cornua.

These are the principal observations made by Professor Owen in his interesting paper, but he also notices one beautiful provision in the structure of the animal which we must not omit. The nostrils of the Giraffe are provided with cutaneous sphincter muscles, and can be shut at will like the eyes. Professor Owen supposes that the object of this mechanism is to keep out the sand when the storms of the desert arise.

Every one must be struck with the beautiful large eye of the Giraffe; and it will be found upon further examination that it is so placed that the animal can see much of what is passing on all sides, even behind it, without turning the head. Thus it is approached with the greatest difficulty; and if surprised, or run down, it can direct the rapid storm of kicks by which it defends itself in the most accurate manner. We need hardly add that the horny hoofs are divided, and that the two small lateral toes generally seen in the true ruminants are wanting.

We now proceed to speak of the history and arrangement of the Giraffe:—In Deut., xiv., where there is an enumeration of meats, clean and unclean, we find (verse 5), among the beasts which the Israelites are permitted to eat, "the hart, and the roebuck, and the fallow deer, and the wild goat, and the pygarg, and the wild ox, and the chamois." So it stands, or with very slight variation, in the more modern English translations. In the black-letter Bible "imprinted at London by Robert Barker, printer to the king's most excellent majestie (1615)," we find the same verse thus written: "The hart, and the roebucke, and the bugle, and the wilde goate, and the unicorne, and the wild oxe, and the chamois." In the 'Physica Sacra,' the verse is thus given in Latin:—"Cervum, Capream, Ibicem, (*a*) Hircocervum, '(*b*) Unicornem, Urum et *Tarandum*;'" and a note adds, "(*a*) Alii legunt Bubalum aut Bovem Sylvestrem, (*b*) Tragelaphum." Opposite to this stands the following version of the same: "Cervum et Capream, Bubalum, Tragelaphum, Pygargum, Otygem, *Camelopardalum*." These are the Tigurine and Vulgate versions. The original word, it appears, is זמר, Zemer, and Scheuchzer observes that Hieronymus, many interpreters, and many versions render the word by *Camelopardalis*, which is the Zurapha, Zerafet, and Zürafet (plur. Zerafi and Zeraif), of the Arabians; Sürnapa, Zürnapa, Zürnepa, of the Turks; an interpretation which renders the Arabians and Jews doubtful whether the flesh, which is said to be hard and difficult of digestion, be permitted by the law. Bochart rejects the term *Camelopardalis*, because that animal is not an inhabitant of either Arabia or Palestine, but of Nubia and Ethiopia, and therefore was long unknown to Europeans. Scheuchzer adds that Aristotle says nothing about the Camelopard or Cameleopard—"de eâ nil prorsus habet Aristoteles"—and that the first of the Greeks who described it was Agatharchides, who lived in the time of the sixth Ptolemy (Philometor). This animal, he continues, was not seen at Rome before the time of Cæsar: "Unde inferre licet, non ignotam fuisse duntaxat Mosis tempore, sed et Alexandri, qui Mose posterior est annis 1200." Wherefore the commentator has recourse to the Cervine or Caprine genus, and selects the *Rupicapra* (Chamois), observing that 'our two versions' read *Tarandum* (the rein-deer, which, he says, in Meninzk. Lex. has the cognomen of *Sürnapa* and *Giraffa*). In Scheuchzer's plate (ccxxix.) of the clean and unclean animals (Levit., xi. 2), the Giraffe does not appear, but at pl. cccxli. (Deut., xiv. 5), he figures a *Cameleopardalis* and *Tarandus*—'Cameel-Pardel' and 'Rennthier,' the former with sharp antelope-like horns, and the latter with a spotted skin and somewhat extraordinary antlers. With the exception of the head and horns, that part of the Camelopard which appears—the hind-quarters are hidden by the other figure—is not bad. Both figures appear to be copies from Jonston, who seems to have copied one of his Camelopards from Gesner. Scheuchzer introduces the body and head of a Camelopard with the same antelope-like horns, but rather more curved in the background of pl. xxxii. (Gen. iii. 21). The commentator in the 'Pictorial Bible,' where a good cut of the Giraffe is given, says, with reference to the word 'chamois,' "The Arabic version understood that the Giraffe was meant here, which is very likely to have been the case; for the Chamois is not met so far to the southward as Egypt and Palestine. The Giraffe or Cameleopard (*Camelopardalis Giraffa*) is a singular as well as beautiful creature found in the central parts of Africa. The Jews had probably many opportunities of becoming acquainted with the animal while in Egypt, as had also the Seventy, who resided there, and who indicate it in their translation of the Hebrew name."

Belzoni notices the Cameleopard on the walls of the sekos of the Memnonium, and on the back of the temple of Erments. In Gau's 'Nubien' (pl. 15) is the representation of a relief, for the general character of which we refer to the work itself, and to the interesting account published in the 'Library of Entertaining Knowledge: British Museum—Egyptian Antiquities,' vol. i. In the procession appears, among other animals, a well-executed figure of a Giraffe led by a man dressed in skins. The author of the useful and amusing book last quoted supposes the relief to represent the booty obtained after a victory.

Rosellini, in his great work on Egypt, gives the coloured engraving of a Pompa, wherein a Giraffe ('M.C.,' No. xxii., fig. 2), the spots on which are very close, is depicted as led by two men, who hold cords tied to the fore legs below what is called, in common parlance, the knee. A green monkey with a red face, &c., and a long tail, is climbing up the Giraffe's neck. The subligacula of the leaders, who appear to be Nubians (?), are different; those of the one are spotted like a leopard-skin, and this man has a dark blue close cap on his head; those of the other show a sort of reticulated pattern, and he wears a close cap with a light ground and light blue spots. And here it is worthy of note that we find in the enumeratiou of the rare animals exhibited in the Pompa of Ptolemy Philadelphus at Alexandria, described in so lively a manner by one of the Deipnosophists (Athenæus, lib. v. c. 8, s. 32), one camelopard—καμηλοπάρδαλις μία.

Whether the ἱππάρδιος (Hippardius—Horse-Pard) of Aristotle (lib. ii., c. 1) be the Giraffe appears to be doubtful, and the prevailing opinion seems to be that he meant by the word some species of Deer. The passage which mentions the ἱππέλαφος (Hippelaphus—Horse-Stag or Horse-Deer)* states that both these animals have cloven feet and the head armed with horns, but that the female of the Hippelaphus has no horns; thereby intimating that the female of the Hippardius had. This however would be equally applicable to the rein-deer.

The celebrated Prænestine pavement, said to have been made by the direction of Sylla, who had held the office of quæstor in Numidia, represents the Giraffe both grazing and browzing, and it seems to be a good opinion that the artists employed to work in mosaic even in Italy and Spain were Egyptian Greeks. Still the animal itself does not appear to have been seen in Italy before the time of Julius Cæsar, who exhibited it among other animals in the Circensian games.†

In his description Pliny appears to have taken the darker parts of the skin of the animal as forming the ground colour, and relieved by the lighter tint. This is probably the same animal as that mentioned by Varro, who alludes to a *Camelopardalis*, as having been lately brought from Alexandria, in figure like a camel and spotted like a panther. The Giraffe afterwards became a not unfrequent and conspicuous part of the Roman shows. Thus the third Gordian had ten at one time. We trace the animal in the writings of Artemidorus, Strabo, Oppian, Heliodorus, and others, till the great blank of literature intervenes.

After the revival of letters, we find in Belon a good description upon tho whole, and a very tolerable figure. In the small 4to. entitled 'Portraits d'Oyseaux, Animaux, Serpens, Arbres, Hommes et Femmes d'Arabie et Egypte, observez par P. Belon du Mans, le tout enrichy de Quatrains, pour plus facile cognoissance des Oyseaux, et autres Portraits' (1557), the figure is given with only the following notice and quatrain above and below it:—'Portrait de la Giraffe, nommée en Latin Camelopardalis: les Arabes l'appellent Zurnapa.' The quatrain is—

> "Belles de corps les Giraffes, et douices,
> Ont en maintien du Chemeau la maniere.
> Leurs pieds sont haults devant et bas derriere;
> Poil blanc et roux; cornes courtes et mousses."

Gillius states that he saw three at Cairo, and gives a description of the animal. Prosper Alpinus relates that he saw a *Camelopardalis*, "quem Arabes Zurnap, et nostri Giraffam appellant," and likens it to a very elegant small horse.

Gesner, who among other synonyms, enumerates *Giraffa* (alias *Gyrapha*, *Girapha*) as the name of the *Camelopardalis*, or *Camelopardus*, or *Camelus Indica*, gives also *Zirafa*, as well as *Nabis* (Æthiopian), *Girnaffa* (Persian), and *Serapha* (Arabian). His figure, which he says is taken from an Italian printed book, by an anonymous author, is evidently made up principally from the descriptions of the ancients. It has antelope-like subrecurved sharp horns, and a short sharp-pointed tail with something of an upward curve, in which may be traced the 'caudam Dorcalidis, id est Capreoli,' as the text has it, attributed to the animal by Oppian. In the 'Additiones' (Icones, &c.) is presented a much better figure, as far as the horns are concerned, but with a neck, and of a height, generally out of all proportion. The drawing is said to have been diligently taken at Constantinople, where the animal had been sent as a present to the emperor of the Turks, and transmitted to a friend in Germany, A.D. 1559. The figure is without spots.

Aldrovandus gives a figure of the animal with its elongated tongue protruded and browzing upon a tree, which, awkward though it be, would be not very far wrong, were it not for the flowing mane and little sharp horns with a curve forwards.

Jonston gives no less than five figures, three with and two without spots, some with and some without manes, under the names of *Camelopardus*, *Camelopardalis*, *Gierafra*, and *Cameli Indici*, but all with sharp horns of various degrees of curvature, besides two long-necked hornless spotted quadrupeds, one designated as *Camelus Indicus versicolor*, the other as *alius Camelus*.

It is not to be wondered at that some of the figures and descriptions given by such writers as the author last quoted cast a doubt upon the very existence of the animal, and it may not be uninteresting, before we proceed to the later writers on the natural history of this extraordinary animal, to note some of the other evidences preserved in old or uncommon books. In the 'Historia del Grand Tamerlane' (Madrid, 1782), "The ambassadors sent by the king of Castile, Henry III. (1403—2nd embassy), to the great Tamerlane, arrived at a town called Hoy, now Khoy, on the confines of Armenia, where the Persian empire commences. At that town they fell in with an ambassador whom the sultan of Babylon had sent to Tamerlane. He had with him as many as twenty horsemen and fifteen camels, laden with presents which the sultan sent to Tamerlane. Besides these there were six ostriches, and an animal called Jornufa (Giraffe), which animal was formed in the following manner:—In body it was of the size of a horse, with the neck very long, and the fore legs much taller than the hinder ones; the hoof was cloven like that of the ox. From the hoof of the fore leg to the top of tho shoulder it was sixteen hands (palmos); and from the shoulders to the head sixteen hands more; and when it raised its neck it lifted its head so high as to be a wonder to all. The neck was thin like that of the stag; and so great was the disproportion of the length of the hinder legs to that of the fore legs, that one who was not acquainted with it would think that it was sitting, although it was standing. It had the haunches slanting like the buffalo, and a white belly. The skin was of a golden hue and marked with large round white spots. In the lower part of the face it resembled the deer; on the forehead it had a high and pointed prominence, very large and round eyes, and the ears like those of a horse; near the ears two small round horns, the greater part covered with hair, resembling the horns of deer on their first appearance. Such was the length of the neck, and the animal raised its head so high when he chose, that he could eat with facility from the top of a lofty wall; and from the top of a high tree it could reach to eat the leaves, of which it devoured great quantities. So that altogether it was a marvellous sight to one who had never seen such an animal before." ('Library of Entertaining Knowledge —Menageries.')

In the 'Principal Occurrents in John Leo (Leo Africanus) his Ninth Booke of the Historie of Africa' (Purchas, lib. vi. c. 1, sec. 9), we find among the animals of Ethiopia, "The *Giraffa*, so savage and wild that it is a very rare matter to see any of them; for they hide themselves among the deserts and woods where no other beasts use to come; and so soon as one of them espieth a man it flieth forthwith, though not very swiftly. It is headed like a camell, eared like an oxe, and footed like a *; neither are any taken by hunters but when they are very young." In the index of the same book we find "*Camelopardalis*, a huge wilde beast;" and a reference to page 1183, where we find (Purchas, lib. vii. c. 8, s. 2) in the same paragraph, where mention is made of the Abassine soil (Abassia, from Fernandez), this sentence:—"Hares, goats, harts, boars, elephants, camells, buffals, lions, panthers, tigres, rhinocerotes, and other creatures, are there seene, and one so huge that a man sitting on horsebacke may pass uprighte under his belly; his shape is like a camell, but his nature divers, feeding on leaves which he reacheth from the tops of trees with his necke stretched forth." In the margin is printed, "This seemeth to be the *Camelopardalis*;" and, indeed, the description will do very well for it, with the exception of the horse and his rider passing "upright under his belly."

Again, in the fifth volume, 'The Sixt Booke, chap. i., of Africa, and the Creatures therein,' and s. 2, "Of the beasts, wild and tame," is mentioned "the *Giraffa*, or *Camelopardalis*, a beast not often seene, yet very tame, and of a strange composition, mixed of a libard, hart, buffe, and camell, and by reason of his long legs before, and shorter behinde, not able to graze without difficultie; but with his high head, which he can stretch forth halfe a pike's length in height, feeds on the leaves and boughs of trees.

In a note is added, "P. Bellon, lib. ii. c. 49, doth largely describe him. (See his description in Moresou and Sandys.) Also Master Sanderson saw one at Cairo, and hath described him in his 'Voyage,' which I have printed." (Tom. i. lib. 9.) Upon turning to the passage (lib. ix. c. 16, s. 2) it appears that Sanderson saw the animal at Constantinople. "The admirablest and fairest beast I ever saw was a Jarraff, as tame as a domesticall deere, and of a reddish deere colour, white brested, and cloven-footed; he was of a very great height, his fore legges longer than the hinder, a very long necke, and headed like a camell, except two stumpes of horne on his head. This fairest animall was sent out of Æthiopia to this Great Turke's father for a present. Two Turkes, the keepers of him, would make him kneele, but not before any Christian for any money. An elephant that stood where this faire beast was the keepers would make to stand with all his four legges, his feet close together, upon a round stone, and alike to us to bend his fore legges." †

* Mr. Ogilby says ('Zool. Proc.' 1836) that *Tragelaphus Hippelaphus* (*Antilope picta* of authors), the Nylghau [ANTILOPEÆ] or Neelghae, and not the Saumer Deer of India, is the animal described by Aristotle under the name of Hippelaphus.

† "Nabin (Pliny, lib. viii. c. 18) Æthiopes vocant, collo similem equo, pedibus et cruribus bovi, camelo capite, albis maculis rutilum colorem distinguentibus, unde appellata Camelopardalis, dictatoris Cæsaris Circensibus ludis primum visa Romæ. Ex eo subinde cernitur, aspectu magis quam feritate conspicua: quare etiam ovis feræ nomen invenit."

* Here there is a word wanting in the original.

† c. xvi.

"By the permission of Almightie God,
Sundrie the personall voyages performed by John Sanderson, of London,

In the 'Museum Tradescantianum' (1656), at the end of the second section, "Four-footed beasts, with some hides, hornes, hoofes," we find "divers horns answering to those by authors attributed to the *Ibex*, *Gazella*, *Hippelaphus*, *Tragelaphus*, *Cervus palmatus*, *Camelopardalis*, &c."

In Ludolf's '*Æthiopia*,' of which there is a curious translation, 'made English by J. P., Gent' (1682), the following paragraph appears in the chapter 'of four-footed beasts':—"The next is the *Camelopardalis*, or Panther-Camel, which is not" (as big) "and hulkie as the elephant, but far exceeds him in tallness. For this beast is so very high that a man of a just statue (stature) reaches but up to his knees, so that it seems very credible what is reported, that a man on horseback, sitting upright on his saddle, may ride under his belly. He derives his name from hence, that he has a long head and a long neck like a camel, but a skin spotted all over like a panther. The Romans, when they first beheld this beast, called it a wild sheep, tho' being more remarkable for its aspect then (than) its wildness or fierceness, as we read in Pliny. By the Abissines, by reason of the smallness of his tayl, he is called Jerata-Kaein, that is, Slender Tayl; by the Italians Giraffa, from the Arabian word Zucaffa (Zuraffa?)."

Hasselquist, who travelled in the years 1749-50-51-52, mentions, in his 'Voyages and Travels,' the *Cervus Camelopardalis*. The Camel-Deer, Belon.; *Camelopardalis Giraffa*, Alpin., Egypt, Zurnap, Arab. "The colour of the whole body, head, and legs of this animal is variegated," says the traveller, "with dark brown spots; the spots are as large as the palm of a man's hand, of an irregular figure, and in the living animal are of various shades. This deer is of the bigness of a small camel; the whole length from the upper lip to the tail is 24 spans. It is met with in the shady and thick woods of Senaar and Æthiopia. N.B. This is a most elegant and docile animal; it has been seen by very few natural historians, and indeed scarcely by any except Bellonius; but none have given a perfect description or good figure of it. I have only seen the skin of the animal, and have not yet had an opportunity of beholding it alive." In the 'Act. Upsal.' the same zoologist gives a very minute description of the animal.

Brisson gave it a generic station, under the name of *Giraffa*, in the first section of his fifth order, consisting of those quadrupeds which have no incisor teeth in the upper jaw, but eight in the lower, and the hoof divided. This first section contains those genera which have simple horns; and, besides the Giraffe, comprises the goats, the sheep, and the oxen.

Our countryman, John Ray, places the Giraffe under his *Cervinum* genus, the fourth of his ruminants, with the deer, as the title implies.

Linnæus, in the last edition of his 'Systema Naturæ' (1766), gives the Giraffe as the first species of his genus *Cervus*, or *Cervus Camelopardalis*, and describes it as being a *Cervus* with very simple horns, and the fore legs or feet longest. "*C.* cornibus simplicissimis, pedibus anticis longissimis." The habitat he gives as Ethiopia and Senaar, and adds, that the animal even then was obscure, and that it is sprinkled with white spots like fawns: "Animal etiamnunc obscurum, adspersum maculis albis, ut cervi juniores." He alludes to its grazing with divaricated legs, but says that its principal food consists of the leaves of trees.

A drawing, which appears to have been a mere rude sketch, nothing worth, together with a notice of the Giraffe, was brought under the observation of the Académie des Sciences (1764). This drawing and notice related to one of these animals which had been found during a journey made in 1762, as far as two hundred leagues northward of the Cape of Good Hope. Buffon notices this as extending the geographical distribution of the Giraffe, which had been confined to Ethiopia by Thevenot and the majority of writers; but this is the principal contribution to the history of the animal in the count's article, which is indeed learned and eloquent, but erroneous in many points, and unnecessarily severe on Hasselquist for the dryness and imperfection of his description. Buffon gives the description of the Swedish naturalist in a note, and though there may be some obscurity in the part relating to the horns when read by one who had never seen the animal—and of this Buffon particularly complains—that very part shows the accuracy of Hasselquist. For instance, Hasselquist, after describing the hairs round the edge of the top of the horns, says, "Apex cornuum in medio horum pilorum obtusus, nudus" (the apex of the horns in the midst of these hairs is obtuse and naked), thus conveying in a few words the real condition of that part of the structure, and showing the acuteness of his observation. But Buffon had no very great love for Linnæus or his pupils; and Sparrman, in his 'Voyage to the Cape,' attacks the French zoologist in no measured terms, exposing with a rough hand his blunders, and appearing resolved to appease the manes of the meritorious Hasselquist for the insult of the count. Buffon's figure is bad, particularly about the horns, and the mane is too long.

merchant, begun in October, 1584, ended in October, 1602, with an historicall description of Constantinople." The second voyage to Constantinople appears to have commenced in 1591, and Sanderson arrived there on Palm-Sunday, "where," says he, "then I remained sixe or seven yeeres, in which time I had the view of many animals." After enumerating some, he commences the paragraph which we have given in the preceding page.

The description of M. Allamand, in his supplement to Buffon's account, taken from the specimen sent by M. Tulbagh, governor of the Cape of Good Hope, and preserved at Leyden, well supplies the defects of Buffon, and he gives accurate measurements. We would particularly call attention to the following observations of M. Allamand:—"Although the horns are solid like those of a deer, I doubt whether they are shed like them: they seem to be an excrescence of the os frontis, like the bone which serves for the core of the hollow horns of oxen and of goats, and it is scarcely possible that they can be detached. If my doubt is well founded, the Giraffe will be a peculiar genus (un genre particulier) differing from all those under which are comprehended the animals who shed their horns and those whose horns are hollow but permanent." Again, he says, "the adult giraffes have in the middle of their forehead a tubercle which seems to be the commencement of a third horn: this tubercle does not appear upon the head of our specimen, which probably was as yet too young to show it." M. Allamand also remarks that in this young specimen the height of the posterior legs equals that of the anterior, and that the mane is three inches in length.

In 'Phil. Trans.' (vol. lx. p. 27) is the following 'Letter on a Camelopardalis found about the Cape of Good Hope, from Captain Carteret to Matthew Maty, M.D., Sec. R. S.,' dated on board of the Swallow, Deptford, April 20, 1769—read January 25, 1770:—

"Sir,—Inclosed I have sent you the drawing of a *Camelopardalis* (Tab. 1), as it was taken off, from life, of one near the Cape of Good Hope. I shall not attempt here to give you any particular description of this scarce and curious animal, as it is much better known to you than it can be to me; but from its scarcity, as I believe none have been seen in Europe since Julius Cæsar's time (when I think there were two of them at Rome), I imagine its drawing and a more certain knowledge of its reality will not be disagreeable to you. As the existence of this fine animal has been doubted by many, if you think it may afford any pleasure to the curious, you will make what use of it you please.

"The present governor of the Cape of Good Hope has sent out parties of men on inland discoveries, some of which have been absent from eighteen months to two years, in which traverse they have discovered many curiosities, which it is to be hoped they will in convenient time communicate to the world. One of these parties crossed many mountains and plains, in one of which they found two of these creatures, but they only caught the young one, of which the inclosed is the drawing, as it was taken off by them; they endeavoured to bring it alive to the Cape Town, but unfortunately it died. They took off his skin, which they brought as a confirmation of the truth, and it has been sent to Holland. These particulars, as well as the drawing, I got from Mr. Barrawke, first secretary to the Dutch Company at that place, in the presence of the governor. I am, Sir, your most humble, most obedient servant,

"PH. CARTERET."

To this is appended the following note:—

"The animal described in this letter is now in the Cabinet of Natural History at Leyden, where I have seen it this year.

"M. MATY."

Then comes the figure, and opposite to it, p. 29:—

"Dimensions of a male *Camelopardalis*, killed in a journey made in the year 1761, through the country of a tribe of Hottentots called the Mamacquas:—

	Ft.	In.
"Length of the head	1	8
Height of the fore leg, from the lower to the higher part	10	0
From the upper part of the fore leg to the top of the head	7	0
From the upper part of the fore leg to the upper part of the hind leg	5	6
From the upper part of the hind leg to the tail	1	6
Height of the hind leg from the upper to the lower part	8	5"

Pennant, in the first edition (1771) of his 'Synopsis of Quadrupeds,' shows to what extent the doubts of the animal's existence had been carried; for, after adverting to its locality, "the forests of Ethiopia and other interior parts of Africa," and its habits, he proceeds:—"I saw the skin of a young one at Leyden well stuffed and preserved; otherwise I might possibly have entertained doubts in respect to the existence of so extraordinary a quadruped. Belon's figure is very good." The specimen here alluded to was most probably that mentioned by M. Allamand and in Captain Carteret's letter.

The travels of Dr. Sparrman occupied a period from the year 1772 to 1776. He gives Allamand's description, and adds the following:—"This animal, when it goes fast, does not limp, as some have imagined, but sometimes paces and sometimes gallops. Every time it lifts up its fore feet it throws its neck back, which on other occasions it holds erect; notwithstanding this, it is by no means slow when pursued, as M. de Buffon supposes it to be, but, on the contrary, it requires a fleet horse to hunt it. In eating the grass from off the ground it sometimes bends one of its knees, as horses do; and, in plucking leaves and small branches from high trees it brings its fore feet about a foot and a half nearer than usual to the hind feet. A *Camelopardalis* which Major Gordon wounded in the leg, so that it could not raise itself from the ground, nevertheless did not show the least signs of anger or resentment; but, when its throat was cut, spurned against the ground with a force far beyond that of any other animal. The viscera resemble those of gazelles, but this animal had no porus ceriferus. The flesh of the young ones is very good eating, but sometimes has a strong flavour of a certain shrub, which is supposed to be a species of *Mimosa.* The Hottentots are particularly fond of the marrow, and chiefly for the sake of this hunt the beast, and kill it with their poisoned arrows. Of the skin they make vessels, in which they keep water and other liquors."

Le Vaillant did not meet with the Giraffe till his second journey into the interior of Africa from the Cape during the years 1783-84-85. But at the end of the second volume of his first journey, which commenced in 1780, he gives figures of a male and female Giraffe, and a compendium of his observations, remarking that it is a kind of anticipation which is owing in some measure to solicitations which he ought to consider as commands. As Le Vaillant appears to be the first well-informed zoologist of modern times who saw the animal in a state of nature, and as he hunted it and brought it down with his own fusil, his account is worthy of particular attention.

"If," says Le Vaillant, "among the known quadrupeds precedency be allowed to height, the giraffe without doubt must hold the first rank. A male which I have in my collection, and of which a figure is given in the eighth plate, measured, after I killed it, 16 feet 4 inches, from the hoof to the extremity of its horns. I use this expression in order to be understood; for the giraffe has no real horns, but between its ears, at the upper extremity of the head, arise in a perpendicular and parallel direction, two excrescences from the cranium, which without any joint stretch to the height of 8 or 9 inches, terminating in a convex knob, and are surrounded by a row of strong straight hair, which overtops them by several lines. The female is generally lower than the male. That represented in the following plate was only 13 feet 6 inches in height; and her incisive teeth, which were almost all worn away, incontestibly proved that she had attained to her full growth. In consequence of the number of these animals which I killed and had an opportunity of seeing, I may establish as a certain rule that the males are generally 15 or 16 feet in height, and the females from 13 to 14 feet. Whoever should judge of the thickness of these animals from the above dimensions would be greatly deceived. The eye indeed that is accustomed to the long full figures of Europe, finds no proportion between a height of 16 feet and a length of 7 feet, taken from the tail to the breast. Another deformity, if it may be called so, makes us contrast the parts before with those behind. The former have a considerable thickness towards the shoulder, but the latter are so thin and meagre that they do not seem formed the one for the other. Naturalists and travellers who speak of the giraffe all agree in making the hind legs only half the length of those before; but did those who assert so really see the animal, or, if they saw it, did they consider it attentively? An Italian author, who certainly never saw it, caused a figure of it to be engraved at Venice, in a work entitled 'Descrizioni degli Animali,' 1771. This figure is formed exactly from the descriptions which had then been published of the animal; but this exactness renders it so ridiculous, that we must consider it, on the part of the Italian author, as a severe criticism on all the accounts which had appeared, and which have been so often repeated." Le Vaillant then goes on to remark that of all the old authors who have treated of this animal, Gillius is the most accurate, who expressly says that the Giraffe has its four legs of the same length; but that the fore thighs are so long in comparison of those behind that the back of the animal appears inclined like the roof of a house. "If," says Le Vaillant, "by the fore thighs Gillius means omoplate, or shoulder-blade, his assertion is just, and I perfectly agree with him." In a note it is added, that among the moderns the most exact engraving is without doubt that which was executed under the inspection of Dr. Allaman, from drawings furnished by Colonel Gordon. After observing that the account of Heliodorus is far from being correct, Le Vaillant continues thus :— "The horns, forming part of the cranium, as I have already said, can never fall off. They are not solid like those of the stag, nor composed of any substance analogous to those of the ox; much less do they consist of hair united, as Buffon supposes. They are simply of a bony calcareous substance, divided by a multitude of small pores like all bones, and are covered throughout their whole length with short coarse hair, which has no resemblance to the soft down that covers the young horns of roe-bucks or stags." The French traveller then notices the defective figures of Buffon and Vosmaer, observing that the defects disgrace and render of no utility to science such false representations, which people very improperly confide in on account of the reputation of the authors who publish them. He states that the Giraffes, both male and female, are spotted in the same manner; and that, without paying attention to the inequality of size, they may easily be distinguished from each other, even at a distance. The male, on a grayish-white ground, has large spots of a dark-brown colour, almost approaching to black; and the female, on a like ground, has spots of a tawny colour, which renders them less striking. The young males are at first of the colour of their mother, but in proportion as they advance in age and size they become browner.

The Giraffes feed upon the leaves of trees, and particularly on those of a *Mimosa* peculiar to the districts which they inhabit. Meadow-grass also forms part of their aliment; but they are not under the necessity of kneeling down to browze or to drink, as some have improperly believed. They often lie down to ruminate or to sleep, which causes a considerable callosity on the sternum, and makes their knees to be covered with a hard skin. "Had nature," says our author in conclusion, "endowed the giraffe with an irascible disposition, it certainly would have had cause to complain; for the means with which it is provided either for attack or defence are very trifling. It is indeed a peaceful and timid animal; it shuns danger, and flies from it, trotting along very fast: a good horse can with difficulty overtake it. It is said that it has not strength to defend itself; but I know, beyond a doubt, that by its kicking it often tires out, discourages, and even beats off the lion. Except upon one occasion I never saw it make use of its horns: they may be considered of no utility, were it possible to doubt the wisdom and precautions employed by nature, whose motives we are not always able to comprehend."

Gmelin, in his 13th edition of the 'Systema Naturæ' (1789), elevates the Giraffe to a genus under the name of *Camelopardalis*, with the following generic characters :—Horns very simple, covered with skin (simplicissima pelle tecta), terminated by a fasciculus of black hairs. Lower incisor teeth (dentes primores inferiores) eight, spatulate, the last deeply bilobated externally. He gives one species, *Camelopardalis Giraffa*, and says that it inhabits Sennaar, between Upper Egypt and Ethiopia, where it has been now seen: that it is rare in Abyssinia, and most rare in more southern Africa; that its haunts are leafy woods; that it is wild, timid, very swift (celerrima), and elegant; that it reposes prone like a camel; that it feeds on grass by divaricating the fore legs, but that its principal food consists of the leaves of trees.

In the third edition of Pennant (1793), several additions are made to the description of the Giraffe, but he does not notice Le Vaillant, though the first part of the travels of the latter, containing the account which we have already given, was published before the issue of the edition and before it left Pennant's hands; for the preface with his signature is dated 'Downing, December 1792.' He alludes to the measurement in the 'Journal Historique,' and, quoting Paterson, describes the horns as one foot and half an inch long, ending abrupt, and with a tuft of hair issuing from the summit, adding that they are not deciduous.

"The height of that killed by Mr. Paterson," he continues, "was only 15 feet. The head is of an uniform reddish-brown; the neck, back, and sides, outsides of the shoulders and thighs, varied with large tesselated, dull rust-coloured marks of a square form, with white septaria, or narrow divisions; on the sides the marks are less regular; the belly and legs whitish, faintly spotted; the part of the tail next to the body is covered with short smooth hairs, and the trunk is very slender; towards the end the hairs are very long, black, and coarse, and forming a great tuft hanging far beyond the tip of the trunk; the hoofs are cloven, 9 inches broad, and black. This animal wants the spurious hoofs. The female has four teats. Mr. Paterson saw six of these animals together; possibly they might have been the male and female with their four young." Pennant then goes on to say that the animal inhabits the forests of Ethiopia, and other interior parts of Africa, almost as high as Senegal; but is not found in Guinea or any of the western parts, and, he believes, not farther south than about 28° 10′ lat., ('Journal Historique'), among the Nemaques (Namaquas) on the northern side of the Orange River, and that it is very timid but not swift. He says, after alluding to the necessity for the animal to divaricate its legs very widely if it would graze, that it therefore lives by browzing the leaves of trees, especially those of the *Mimosa* and a tree called the wild apricot. "When it would leap," he adds, "it lifts up its fore legs and then its hind, like a horse whose fore legs are tied. It runs very badly and awkwardly, but continues its course very long before it stops. It is very difficult to distinguish this animal at a distance, for when standing they look like a decayed tree, by reason of their form, so are passed by, and by that deception escape." Immediately after this, Pennant repeats verbatim the sentence from the first edition, stating that he had seen the skin of one at Leyden, otherwise he might have entertained doubts, &c. The figure given in this edition is evidently taken from a stuffed specimen, but comes much nearer to the animal than any of those we have hitherto mentioned, except Le Vaillant's. Mr. Paterson who is here mentioned was sent to the Cape as a botanist by Lady Strathmore, and he brought to this country, on his return, the first entire specimen of a Giraffe recorded. Lady Strathmore gave it to John Hunter, in whose museum it long was, and the Trustees of the Museum of the Royal College of Surgeons transferred the skin to the British Museum when that of the college was cleared of the stuffed skins to make way for preparations more in unison with its general zootomical character. This skin, now almost entirely hairless, is still to be seen in the British Museum, where there are also four other specimens and an entire skeleton.

The animal, after this, still continued to be noticed in books of Natural History, but nothing worthy of notice occurs to us, though the reader may be referred to the 'Zoography' of Wood, and especially to Shaw's 'Zoology,' for the information there collected.

Cuvier, in the first edition of his 'Règne Animal,' (1817), speaks of the Giraffe, *Camelopardalis*, as having for its characters conical persistent horns in both sexes, covered with a hairy skin, and as being one of the most remarkable animals on account of the length of its neck, the disproportioned length of the fore legs, the osseous tubercle on the chanfrein, &c., but dismisses it with a very brief notice. He places it between the Deer (*Cervus*) and the Antelopes (*Antilope*).

Major (now Lieutenant-Colonel) Hamilton Smith, who has devoted so much attention to the Cervine and Antelopine groups, observes that the Giraffe stands isolated among the Ruminating animals in family, genus, and even species: its characters, he remarks, offer a mixture of several genera; among which the followers of the quinary system may select whether to class it, with Illiger, among Cameline, or, with other naturalists, amongst Cervine or Antelopine animals. The same zoologist points out its assimilation with the camels by the length of the neck, the callosities on the sternum and knees, and the want of spurious hoofs, an approximation so obvious that it did not escape the notice of the ancients; but, he adds, that the pedunculated form of the frontal process, in the shape of horns, recalls that character in the Muntjak Deer, while the stiff hairs which crown their summits seem to want only the gluten to cement them into true horns and embody it in systematic arrangement with the *Cavicornia*. From a comparison of the characters which Colonel Smith institutes, he thinks that the Giraffe appears most naturally placed immediately after the Muntjaks, and before the family of *Cavicornia*, or those Ruminants which are distinguished by the possession of true horns.

M. Lesson, in his 'Manuel' (1827), places the Camelopardinées between the Cervules (*Cervus Muntjak*, *Cervus moschus* or *moschatus*, and *Cervus subcornutus*) and the Tubicornes (Antelopes, &c.).

Cuvier, in his last edition of the 'Règne Animal' (1829), appears to take the same view of the case as Lieutenant-Colonel Smith, for he there places the Giraffe between the Muntjak and the Ruminants à Cornes Creuses, the first genus of which is *Antilope*. The character assigned to the genus in this edition differs somewhat from that given in the former one, for Cuvier, who seems to have been acquainted with Dr. Rüppell's interesting memoir above alluded to, adds that the bony core (noyau osseux) of the horns is articulated in youth upon the os frontis by a suture, and that in the middle of the chanfrein is a tubercle or third horn, larger and much shorter, but equally articulated by a suture. He still keeps the observation as to the disproportioned height of the fore legs.

Fischer, in his 'Synopsis,' introduces the Giraffe (*Camelopardalis*) between *Cervus* (*Cervus Guineensis*, Linn., *C. minutus*, Blainv.) and *Antilope* (*A. cervicapra*). He notices the opinion of M. Geoffroy, that the Giraffe of Senaar differs in species from that of the Cape, and he alludes to the following names of the animal:—Jiratalla Amhar; Deba of the Æthiopians; Naip of the Hottentots; Impatoo of the Bosjesmans.

Mr. Swainson, 'Classification of Quadrupeds' (1835), appeals to the opinion and views of Colonel Smith, as confirming the station assigned to the *Camelopardæ*, in his tabular exposition of the families of Ruminants, namely:—

Tribe *Ruminantes*. The Ruminating Quadrupeds.

1. Sub-typical.	Horns sheathing; form gracile, slender.	*Antilopidæ.*	Antelopes.
2. Typical.	Horns sheathing; form heavy; robust.	*Bovidæ.*	Oxen.
3. Aberrant Group.	Horns solid, deciduous.	*Cervidæ.*	Stags.
	Horns wanting; fore legs shorter than the hinder.	*Moschidæ.*	Musks.
	Horns very short, covered with a skin.	*Camelopardæ.*	Giraffes.

The following is Mr. Swainson's definition of his family *Camelopardæ*:—"Frontal processes (in both sexes) prolonged in the shape of horns, covered with hairy skin, which is continued from the scalp, and terminated by long hard bristles." "*Camelopardalis*, Ant., cutting teeth, $\frac{0}{8}$; canine none; grinders, $\frac{6}{8}$. Head long; upper lip entire; lachrymary sinus wanting; neck enormously long, with a short mane; the anterior parts much elevated; back sloping; legs slender, the hinder ones shortest; tail tufted. 2. Sp. Africa. 1. *C. antiquorum*, Sw., Northern Giraffe. 2. *C. australis*, Sw., South African Giraffe. The ruminants are united by this genus and *Camelus* to the *Solipedes*." The family is accordingly placed in this part of the work, between the *Moschidæ* and the tribe *Solipedes* (single-hoofed quadrupeds), the first genus of which, in Mr. Swainson's arrangement, is *Camelus*. Mr. Swainson adds, that there seems good reason for believing that a third species of Giraffe exists in the interior of Africa.

In December 1836 Mr. Ogilby divided the *Ruminantia* into the following families:—1, *Camelidæ*; 2, *Cervidæ*; 3, *Moschidæ*; 4, *Capridæ*; 5, *Bovidæ*. The genus *Camelopardalis* is placed by this zoologist, to whom we are indebted for much and valuable information concerning the Ruminants, as the first of the *Cervidæ*, with the following characters:—Horns, in both sexes, persistent (perennia), simple, covered with skin. Rhinaria, none. Lachrymal sinuses, none. Interdigital fossæ, small. Inguinal folliculi, none. Teats, four. Two species are recorded under the names of *C. Æthiopicus* and *C. Capensis*. The other genera admitted by Mr. Ogilby into the family *Cervidæ* are *Tarandus*, *Alces*, *Cervus*, *Capreæ*, and *Prox*.

The main result of Professor Owen's observations (1838) is to agree with Cuvier in placing *Camelopardalis* between *Cervus* and *Antilope*, and he thinks somewhat nearer the deer. He finds that the organs of relation are those chiefly modified in correspondence with the peculiar geographical position and habits of the Giraffe, the organs of nutrition differing but little from those of other horned Ruminants.

Dr. Gray places his tribe *Giraffina* after the *Bovina* and before the *Cervina*, in the order *Ungulata*.

We must now trace the reappearance of the living animal in Europe. M. Lesson states that the first were an offering by the Prince of Damascus to the emperor Frederick II., and described by Albertus Magnus, under the name of Seraph and Anabula. The author of the 'Menageries' remarks that, till the year 1827, when a Giraffe arrived in England and another in France, the animal had not been seen in Europe since the end of the 15th century, when the Soldan of Egypt sent one to Lorenzo de' Medici. This individual was represented in the frescoes at Poggio Acajano, a villa belonging to the grand duke of Tuscany, between Florence and Prato. It was, the author adds, very familiar with the inhabitants in the former city, living on the fruits of the country, particularly apples, and stretching up its long neck to the first-floors of the houses to implore a meal. Of the comparatively late arrivals, another was at Venice in 1828, and a fourth was sent to Constantinople, but died there. These animals, according to the same authority, were all presents from the Pasha of Egypt. The Giraffe sent to the French menagerie did well: that presented at the same time to George IV. was the shortest and weakest. [The consuls of each nation drew lots for the choice.] She was never in good health and had been roughly treated, and though she had grown 18 inches up to June 1829, she sank gradually and died in the autumn of that year.

The Zoological Society of London had entered into a contract for the purchase of Giraffes, and in 1836 four of these animals (three males and one female) were safely brought from the south-west of Kordofan, where they were captured, to the gardens of the society at the Regent's Park. The following account of the capture of these animals is given by the author of 'Zoological Anecdotes:'—

"M. Thibaut quitted Cairo in April 1834, and after sailing up the Nile as far as Wadi Halfa, the second cataract, took camels and proceeded to Debbat, a province of Dongolah, whence he started for the desert of Kordofan.

"Being perfectly acquainted with the locality, and on friendly terms with the Arabs, he attached them still more by the desire of profit. All were desirous of accompanying him in the pursuit of the giraffes, for up to that time they had treated them solely for the sake of their flesh, which they ate, and the skin, of which they made bucklers and saudals. The party proceeded to the south-west of Kordofan, and in August were rewarded by the sight of two beautiful giraffes; a rapid chase of three hours, on horses accustomed to the fatigues of the desert, put them in possession of the largest of these noble animals; unable to take her alive, the Arabs killed her with blows of the sabre, and cutting her to pieces, carried the meat to their head-quarters, which had been established in a wooded situation—an arrangement necessary for their own comfort, and to secure pasturage for their camels. They deferred till the following day the pursuit of the motherless young one, knowing they would have no difficulty in again discovering it. The Arabs quickly covered the live embers with slices of the meat, which M. Thibaut pronounces to be excellent.

"On the following morning the party started at daybreak in search of the young giraffe, of which they had lost sight not far from the camp. The sandy desert is well adapted to afford indications to a hunter, and in a very short time they were on the track of the object of their pursuit; they followed the traces with rapidity and in silence lest the creature should be alarmed whilst yet at a distance; but after a laborious chase of several hours through brambles and thorny trees, they at last succeeded in capturing the coveted prize. It was now necessary to rest for three or four days, in order to render the giraffe sufficiently tame; during which period an Arab constantly held it at the end of a long cord; by degrees it became accustomed to the presence of man, and was induced to take nourishment, but it was found necessary to insert a finger into its mouth to deceive it into the idea that it was with its dam; it then sucked freely. When captured its age was about nineteen months. Five giraffes were taken by the party, but the cold weather of December 1834 killed four of them in the desert on the route to Dongolah; happily that first taken survived, and reached Dongolah in January 1835, after a sojourn of twenty-two days in the desert.

"Unwilling to leave with a solitary specimen, M. Thibaut returned to the desert, where he remained three months, crossing it in all directions, and frequently exposed to great hardships and privations; but he was eventually rewarded by obtaining three giraffes, all smaller than the first. A great trial awaited them, as they had to proceed by water the whole distance from Wadi Halfa to Cairo, and thence to

Alexandria and Malta, besides the voyage to England. They suffered considerably at sea, during a passage of twenty-four days in very tempestuous weather, and on reaching Malta in November they were detained in quarantine twenty-five days more; but despite all these difficulties they reached England in safety, and on the 25th of May were conducted to the gardens. At daybreak the keepers and several gentlemen of scientific distinction arrived at the Brunswick Wharf, and the animals were handed over to them. The distance to the gardens was not less than six miles, and some curiosity, not unmingled with anxiety, was felt as to how this would be accomplished. Each giraffe was led between two keepers by means of long reins attached to the head: the animals walked along at a rapid pace, generally in advance of their conductors, but were perfectly tractable. It being so early in the morning few persons were about, but the astonishment of those who did behold the unlooked-for procession was ludicrous in the extreme. As the giraffes stalked by, followed by M. Thibaut and others in Eastern costume, the worthy policemen and early coffee-sellers stared with astonishment, and a few revellers, whose reeling steps proclaimed their dissipation, evidently doubted whether the strange figures they beheld were real flesh and bone, or fictions conjured up by their potations; their gaze of stupid wonder indicating that of the two they were inclined to the latter opinion.

"When the giraffes entered the park, and first caught sight of the green trees, they became excited and hauled upon the reins, waving the head and neck from side to side, with an occasional caracole and kick-out of the hind legs, but M. Thibaut contrived to coax them along with pieces of sugar, of which they were very fond, and he had the satisfaction of depositing his valuable charges without accident or misadventure in the sanded paddock prepared for their reception. The sum agreed on with M. Thibaut was 250*l.* for the first giraffe he obtained, 200*l.* for the second, 150*l.* for the third, and 100*l.* for the fourth—in all 700*l.*; but the actual cost to the society amounted to no less than 2386*l.* 3*s.* 1*d.*, in consequence of the heavy expenses of freight, conveyance, &c."

One of these animals (a male) died shortly after its arrival. In 1838 the following were the measurements of the three survivors:—

	Height as far as reach.		Wither.		Rump.	
	Feet.	Inches.	Feet.	Inches.	Feet.	Inches.
Guib Allah (male) . .	13	8	7	11	6	11
Selim (male) . . .	13	0	7	5½	6	7
Zaida (female) . . .	12	11	7	4	6	7

When they arrived at the gardens on the 24th of May 1836, Guib Allah could reach only to 11 feet 6 inches, so that he has grown since that time 2 feet 2 inches. The others have grown in proportion. The length of the mane in one of the males and in the female is 2¾ inches, and in the other male 2½ inches.

Since this time the female has produced several young ones, which have been sold, and are still living in various parts of the world. They seem to bear confinement very well, although it should be remembered that their apartments in the Society's gardens are very airy and well ventilated. Two females have since been added to the collection in the gardens.

They are fed principally on the best hay, placed in high racks; they like a carrot, and are very fond of onions; lump-sugar is also a favourite treat to them. They each eat about 18 lbs. of food a day, and drink four gallons of water.

The erroneous statement that the fore legs are longer than the hind legs has been repeated so frequently and so lately by authorities which deservedly have weight, that it becomes necessary to give the result of examination of the skeleton. In reality the hind legs, taking the limbs only from their setting on, are longer than the fore legs by about one inch. A measurement taken from the head of the humerus to the end of the ungueal phalanges in the fore foot, gives an inch less in length than a measurement taken from the head of the femur to the end of the ungueal phalanges in the hind foot.

Neither Mr. Swainson nor Mr. Ogilby gives any specific characters for the two species named by them, and but one species is recognised by Dr. Gray. If, as Professor Owen's observations tend to show, there is no third horn in the forehead of the northern male giraffes, we do not exactly see on what the specific character is to rest. The dark colour of the adult male of Southern Africa, if it should prove to differ from that of the northern male, would not, it is submitted, sanction more than variety. The specimens presented by Mr. Burchell to the British Museum came from Kosi Fountain, and the difference between the dark spots of the male and the tawny spots of the female s strongly marked. The specimen from Central Africa presented by Colonel Denham is very young, and the spots are bright yellowish tawny. Mr. Steedman, in his 'Wanderings and Adventures in the Interior of Southern Africa' (1835), says that the giraffes are found on the open plains several days' journey to the north of Litakou in small troops of six or ten individuals, and that they feed principally upon the various dwarf species of *Acacia** which grow abundantly in the arid deserts. The writer adds that, though formerly found within the boundaries of the Cape of Good Hope, they have not for many years past been known to pass the Gareep, or Orange River, which separates it from the Griqua and Coranna country; and he notices their moving the fore and hind feet of the same side, and then the opposite pair alternately, exhibiting the pace which is usually called an amble in horses.

* Sir Everard Home states that the favourite species is *Acacia Xariffiana*, named from Zariffa, the Giraffe. Le Vaillant says that the sort of *Mimosa* on which it feeds is called 'Kanaap' by the natives, and 'Kameldoorn' by the colonists.

Giraffa (*Camelopardalis Giraffa*).

Those who wish to obtain further information on the Giraffe should consult the works of Klein, Schreber, Vosmaer, Zimmerman, and Lichtenstein; also Sir W. C. Harris's 'Portraits of the Game and Wild Fowl of South Africa,' and Captain Gordon Cuming's 'Adventures.'

GIZZARD, the muscular or pyloric division of the stomach in birds. In these animals the stomach is divided into two parts. The lower œsophagus (the canal which is continued from the crop to the stomach) first dilates into a cavity called the proventriculus, or glandular division of the stomach; this has a very vascular lining membrane, and is furnished with numerous large follicles, or glands, placed between the mucous and muscular coats, which secrete a solvent fluid very similar to the gastric juice in *Mammalia*. This first division of the stomach mostly terminates immediately in the gizzard, which is situated below the liver, on the left side of the abdomen, resting on the intestines. This organ has more or less a lengthened form, and is furnished at its upper part with two openings, the cardiac and pyloric, which are close together; the former communicates with the proventriculus and the latter with the intestines. Below those openings the gizzard dilates into a pouch, in the middle of the anterior and posterior sides of which is a tendon to which muscular fibres are attached. In birds of prey, whose food is easily digested, the gizzard is a mere membranous cavity; but in graminivorous birds it is furnished with muscles of great power, which are arranged in four masses: the two largest, which are situated anteriorly and posteriorly, are connected with the central tendons, and are called the digastric muscles; between these are two thinner ones.

The lining membrane of the gizzard is very hard and thick, and opposite to the digastric muscles two callous spots are formed by the pressure and friction. The muscles take up so much room in the stomach of graminivorous birds that the crop is a necessary appendage to the gizzard, and transmits the food, little by little, to be digested. The food is triturated in the gizzard by the immediate agency of hard foreign bodies, as sand and gravel, which the birds swallow; these bruise the grains of corn by the action of the muscles, and deprive them of their vitality, when the gastric juice acts upon and dissolves them. The pebbles thus perform the vicarious office of teeth.

Hunter inferred that the action of the great digastric muscles of the stomach in birds was rotatory, and says, "Although the motion of the gizzard is hardly visible, yet we may be made very sensible of its action by putting the ear to the side of a fowl while it is grinding its food, when the stones can be heard moving one upon another." The pyloric or intestinal orifice of the gizzard is furnished with a valve, which is of considerable size in those birds which swallow large stones, as the ostrich; it prevents them from passing into the intestines, and it also keeps the food in the stomach until it has undergone a sufficient degree of trituration or mastication to fit it for nutrition.

GLACIERS, a French word received into our language, and which must not be confounded with Glacière, which has a different signification.

The glaciers, as defined by Saussure, are those eternal masses of ice which are formed and remain in the open air in the valleys and on the slopes of lofty mountains.

In speaking of glaciers we generally refer to those of the Alps, as being the best known, though there are many in other places. The glaciers of the Alps have been frequently described by travellers, geographers, and naturalists, but by none in so much detail as by Saussure and Gruner.

If, says Saussure, a spectator could be placed at a sufficient height above the Alps to embrace at one view those of Switzerland, Savoy, and Dauphiné, he would see a mass of mountains intersected by numerous valleys, and composed of several parallel chains, the highest in the middle, and the others decreasing gradually as they recede. The central and highest chain would appear to him bristled with craggy rocks, covered even in summer with snow and ice in all those places that are not absolutely vertical; but on both sides of the chain he would see deep and verdant valleys, well watered and covered with villages. Examining still more in detail, he would remark that the central range is composed of lofty peaks and smaller chains, covered with snow on their tops, but having all their slopes that are not very much inclined covered with ice, while the intervals between them form elevated valleys filled with immense masses of ice, extending down into the deep and inhabited valleys which border on the great chain. The chain nearest to the centre would present to the observer the same phenomenon, but on a smaller scale, beyond which he would see no more ice, nor even snow, save here and there on some of the more elevated summits.

From what precedes, continues Saussure, I recognise two kinds of glaciers, quite distinct from each other, and to which all their varieties may be referred. The first are contained in the valleys more or less deep, and which though at great elevations are still commanded on all sides by mountains higher still; while the second are not contained in the valleys, but are spread out on the slopes of the higher peaks.

The distinguishing features of the two kinds are the greater extent and depth of the former, and the greater compactness of the mass; but as these circumstances seem to depend on the situation of the glaciers, as is proved by the insensible passage of the one kind into the other in many localities, the distinction of Saussure seems to have little foundation.

The formation of the glaciers, whatever are their position and appearance, is due to the great quantity of snow which falls in the high and cold regions of the mountains, and which the heat of summer can but partially thaw. When the slopes of the lofty peaks are very rapid, the snow, being unable to rest upon them, slips down into the valleys in the form of avalanches; and this being added to what falls directly into the valleys, there is accumulated an enormous quantity that becomes compressed by its own weight. This snow is subsequently converted into a kind of ice by the following process:—The rains which occasionally fall, and the water resulting from the partial melting of the snow in the warmer months, percolates the mass, steeping it throughout; and in this state, being seized by the cold of the succeeding winter, it is consolidated into a glacier. It will however be easily conceived that the ice so formed is very different from that found in ponds or lakes; it has neither the hardness, the compactness, the solidity, nor the transparency of the latter, but is, on the contrary, porous and opaque. The water in filtering through the mass not being able to drive out all the air lodged in the interstices, this air, together with that which is liberated during the subsequent congelation, collects into bubbles of various forms and sizes, destroying the transparency and cohesiveness of the mass. With regard to the snow which rests on the slopes, it is evident that it will be subject to the same effect of rain and warmth as that in the valleys, but, from the very position in which it lies, the water in great part runs off, or is only retained towards the bottom of the slope, whence it results that the glaciers so situated are in general of much looser texture than the glaciers of the valleys. It is only towards the bottom, where the water accumulates, that the ice of the former acquires a consistence equal to that of the latter. This solidity decreases as you ascend, till towards the top there is nothing but snow.

The surface of the glaciers depends entirely upon the ground on which they rest. When the bottom is even, or but slightly inclined, the surface of the glacier, though rough and granulated, is also even, presenting but few crevices, and these not wide; but in proportion as the bottom is inclined or rugged the surface is abrupted and uneven. Ebel, who follows Saussure, says, that wherever the slope exceeds 30 or 40 degrees, the beds of ice break into fragments, which get displaced, upheaved, and piled together in every variety of fantastic form, and exhibit immense chasms many feet in breadth, and often more than 100 feet deep.

The splitting of the ice on a change of weather, or in consequence of unequal pressure on an uneven bottom, shakes the very hills, and produces a noise which, reverberated from the mountains, sounds like thunder. The breadth and depth of the chasms thus occasioned vary considerably according to circumstances. Sometimes their dimensions are rapidly increased, either from the slipping away of the lower mass while the upper remains stationary, or in consequence of the erosion of the water running down them from the thawing of the surface; and at other times they are suddenly closed up by the descent of the upper portion against the lower, which is fixed. The ice at those fissures down which the water flows freely is generally transparent, and is observed to be of a greenish colour towards the top and bluish towards the bottom. These clefts are frequently hidden by a covering of snow, which renders them exceedingly dangerous.

Along the anterior edge and lateral margins of some of the larger glaciers there are masses of débris accumulated into the form of long dykes or parapets, which in the Tyrol are known by the name of 'trockne muren,' and in Savoy by that of 'morain,' which has more generally prevailed. In Iceland, where the glaciers are called 'jokül,' the moraines are named 'jokülsgiärde.' The formation of the moraines is easily conceived. When the rocks bordering the glaciers are themselves bare of snow or ice, in consequence of the rapidity of the slope, and are schistose or stratified, they are easily disintegrated by the alternate action of wet and frost, heat and cold, and the fragments thus detached roll down to the lateral edges of the glacier, where the greater part is stopped, while some isolated blocks are urged farther towards the middle. The general inclination of the glacier and its progressive motion downwards also collect a quantity of these débris along the anterior boundary of the ice-field, so that in some cases the whole glacier is entirely surrounded by a moraine. Wherever the mountain-slopes are protected by a glacier of their own, or where the rock is of compact indestructible granite, no moraine is formed. Thus it happens that some glaciers have a moraine on each side, others on one side only, and some none at all. Occasionally also a moraine is found where none could have been formed, in which case it is one that has been brought down from a higher station by the motion of the glacier, as is evident from the nature of the débris. These moraines sometimes attain a height of a hundred feet. It is observable however that when the glaciers have diminished in size, the moraine is above the ice-field; and when, on the contrary, the glacier has increased the moraine is lower than the ice, and in some cases the moraine and the ice are on a level.

M. Agassiz, of Geneva, in a paper on glaciers, moraines, and erratic blocks, published in the 'Bibliothèque Universelle,' No. 24, 1837, has called attention to the existence of moraines at the height of several hundred feet above the bottom of the superior Alpine valleys, where there are no longer any glaciers; but in descending into the lower valleys they are found in succession as high as twelve, fifteen, and eighteen hundred feet. They may even be observed at two thousand feet above the bed of the Rhône, in the neighbourhood of St. Maurice, in the Vallais, and can also be traced at a great height round the Lake of Geneva: from this fact and other collateral circumstances M. Agassiz concludes that at one time the glaciers covered the whole of the plains of Switzerland to a height of 3300 feet above the level of the sea, or 2155 feet above the present surface of the Lake of Geneva, and extended as far as the Jura. To account for the existence of such masses of ice he supposes the alternate cooling and heating of the globe at distant but given periods. He appeals to fossil remains in confirmation of his theory, and tries to explain the existence of the erratic blocks of the Jura by supposing them to be the transported moraines of his immense glaciers.

Besides the bordering moraines there are long and high ridges formed of fragments of rocks, boulders, sand, and earth, in the middle of the glaciers, and at a considerable distance from the margins, to which however they are generally parallel. These banks, which in the German cantons of Switzerland are called 'gufferlinien,' are sometimes numerous and high. Thus, in traversing the great ice-field above Montanvert, Saussure crossed four or five of them which were 30 or 40 feet high, an elevation due in part to the quantity of the débris, and in part to the sinking of the surrounding ice, which thaws, while that under the heap, sheltered from the sun, remains unthawed. The glacier of Rosboden is said to exhibit the greatest number of these ridges, and of the largest dimensions. The formation of these banks is thus explained. The glacier progressively slipping down upon the inclined bottom of the valley recedes from the sides, carrying part of the lateral moraine along with and upon it. This retreat often leaves a considerable space, particularly in the wider valleys, between the foot of the mountains and the edge of the glaciers, which space, during the succeeding winter, becomes filled up with fresh snow, which is converted into ice by the process already described and on which a new moraine is collected. This recedes like the first, and so on; so that were it not that the moraines of the opposite sides sometimes become confounded into one, and because the motion of the ice on the irregular slopes of the valley disturbs the order and parallelism of the banks, they might serve to determine the age of the glaciers.

In winter, as well as in summer, there is continually a quantity of water flowing out from the lower parts of the glaciers, though much less abundantly in the former than in the latter season. This water proceeds from the thawing of the under surface of the glacier, occasioned by subterraneous heat. In the winter it oozes from under the ice in small streamlets; but in the spring and summer months, when it is greatly increased in quantity, it bursts away the ice from before it, and gushes out in plenteous streams from the caverns it has excavated; some of these grottoes are 100 feet high, and from 50 to 80 feet wide, presenting very various and sometimes highly picturesque appearances. The torrents of the glaciers are remarkable for the whitish-blue colour of their waters, which they maintain for a distance of some leagues.

There is a phenomenon, which the Germans call 'gletschergeblase,' which results from the sudden escape of the air imprisoned beneath the glaciers. On a change of temperature this escapes through the crevices in strong currents of insupportably-cold wind, driving like snow-dust the fine icy particles with which it is loaded.

All the Alpine valleys being inclined planes, it is natural to suppose that the glaciers must slip down by their own weight, whenever any circumstance destroys their adhesion to the sides and bottoms of the valleys. This adhesion is constantly diminished, even in the depth of winter, by the natural warmth of the earth, which thaws the under surface of the glacier; but as this takes place only in those parts where the great thickness of the ice protects the soil from the effects of external cold, the mass by this action is but partially disengaged, and therefore still maintains its position. But when the warmth of summer heats the soil all around, and thaws the ice at its surface and edges, the liberation of the glacier goes on with rapidity, aided as it is moreover by the erosion of the underflowing currents, and the abrasion of the lumps of ice and the stones which they bear along. Then it is that the whole mass, obeying the impulse of gravity, slips down and invades the fertile valleys below, presenting the singular spectacle of an ice-field terminating on flowery meadows and contiguous to rich harvests. The limits which the descending glaciers attain are subject to variation.

Great attention has been lately given to the causes of the descent of glaciers. The hypotheses by which the descent of the vast masses of frozen snow down the valleys of the Alps and other mountainous regions has been explained, or attempted to be explained, are essentially two. First, the original notion of Saussure, put in its most original form, that the glacier-masses descended the valleys by the force of gravity; and secondly, the later notion of Charpentier, that the icy masses were pushed down the valleys by an internal expansion caused by congelation of water in their internal cavities. Each of these original notions takes at least two forms. Saussure's hypothesis, indeed, appears in three modifications of importance.

1 A. The view of Mr. R. Mallet, communicated to the Geological Society of Dublin, recognises the descent of the glacier by gravity, but adds the hydrostatic pressure of water below the glacier—upward and forward; and it is impossible to deny to this speculation the merit of removing some considerable difficulty in the reception of the general hypothesis of Saussure.

1 B. The view of Professor James Forbes, who, besides noticing peculiar structures (the blue bands) in the glacier ice, and measuring the velocity of glacier movements in different parts of the valley, and in the central and lateral parts of the 'ice-current' (if we may so speak), has proved the bending of the ice from a straight transverse line during its movements; and has, by means of artificial preparations, imitated some of the peculiar glacial structures. His view is, that glaciers descend the valleys in consequence of so much mutual yielding and adjustment (plasticity) of their parts as to entitle them to be regarded as viscous or semifluid masses, flowing slowly under the influence of gravity.

1 C. Mr. Hopkins, recurring to the original notion of Saussure, maintains the mechanical probability of the glaciers sliding down their containing valleys, as solid bodies; that is to say, sliding in consequence of the general slope of the valley, and not in consequence of the internal displacements and readjustments of the icy mass. Displacements and readjustments happen in this view no less than in Mr. Forbes's hypothesis. The icy mass is subject to extension, to flexure, and fracture under tension, and a variety of accidents, which Mr. Hopkins has employed to explain the unequal rates of movement, the varying forms of fissures, &c. in glaciers. Ice may be regarded as in a certain degree plastic, since it is flexible; but none of these things interfere with the essential condition of this hypothesis, namely, the sliding of the whole ice-mass on its bed. This sliding is in a great measure due to the perpetual slow fusion of the lower surface of the ice, which leaves it in a constant state of disintegration, &c. Mr. Hopkins has made experiments on the sliding of ice; from which it results, that even at angles of inclination from the horizon much below 1 degree, the movement of the ice masses on a rough flagstone, while the lower surface was subject to slow fusion, was very discernible, and found to follow a simple law proportioned to the sine of the angle of inclination.

2 A. The second branch of the hypothesis alluded to, originating with Charpentier, has further ramified into two forms. Charpentier thought the congelation of water in many fissures of the glacier must necessarily urge portions of it forward in the direction of least resistance. But as the glacier is sliding by day and by night, in summer and in winter, sliding unequally in different parts of its descent, and not with such an order of inequality as fits to the hypothesis; and as there is no assignable reason (in this hypothesis) for the formation of new fissures, and the continuation of the process, this whole speculation (the dilation hypothesis) has been abandoned.

2 B. Another form has been given to it by M. Agassiz. This eminent explorer of the Alpine glaciers ascribes their onward movement to congelation of water, not in the cavities of Charpentier, but in minute capillary fissures and spaces among the granular constituent masses of the glacier. With such a power of expansion, altogether independent of gravity, M. Agassiz esteemed it possible to allow of the movement of glaciers, even across level countries, and thus to account for many geological phenomena difficult to be otherwise explained, as erratic blocks and other diluvial phenomena. Mr. Hopkins has, however, exclusively shown that by the means supposed no such power of onward movement can be exercised. Mr. Forbes has proved the actual phenomena of glaciers to be inconsistent with the assumption of such congelation as a cause and with the effects ascribed to it by Agassiz. It is clear from all experiments and mechanical reasonings, that gravity causes the descent of glaciers; but there remain some further researches to be made into the true internal structure of ice, and the true state of the lower surface of glaciers, before we can regard the inquiry as complete.

The most recent writers on the phenomena of the glaciers are the Messrs. Schlagentweit, who have published a work on the 'Physical Geography of the Alps.'

The investigations of Agassiz and others into the history of the glaciers of the Alps, &c., and their former greater extension, have rendered it very probable that this enormous ice-power has been actively at work in early geological periods in situations where now no fields of ice ever occur. Observations of effects such as glaciers are known to produce on surfaces which they traverse; smoothed and rounded rocks—grooved surfaces—striation parallel to the grooves—appear to require the existence and movement of glaciers down some of the valleys which intersect the Snowdonian, the Cumbrian, and Irish mountains. One of the effects attendant on glaciers is the transport of detritus on the surface of the ice till it melts, or in the case of the glacier meeting the sea, breaks off in an iceberg to be drifted by oceanic currents. It is believed by Agassiz that the immense single blocks of stone which lie on the Jura, opposite the valleys of the Alps, have been deposited there by glaciers, not drifted by water-currents, and this speculation he has applied to far greater areas and more difficult cases, such as the accumulation of erratic blocks, gravel mounds, and diluvial heaps in level regions like those which margin the ancient tertiary Bay of Dublin, or abound in the central plains of England. From so great an extension of this speculation, founded as it is on an erroneous hypothesis of glacial movement, Mr. Hopkins's demonstrations warn us to dissent; but if, as may be easily believed, the ancient glacier streams of Cumberland delivered the detrital blocks of Shap and Carrock into the sea by the breaking off of icebergs, these may have been drifted by currents to Staffordshire, to the mouth of the Tyne, and the valleys of York and Holderness.

It may be objected that for such an icy covering to Snowdon and Skiddaw, a great reduction of climate is necessary, and that this is not consonant with the general tenor of geological inferences, which point to more elevated temperatures in early periods. But the reply is easy. The evidence of warm climates in northern zones relied on by geologists applies to far earlier periods; and in respect of this comparatively late period, a reduction of temperature to the extent required for the production of glaciers on the mountains of Wales and Cumberland is perfectly possible by a mere change of the disposition of land and water—since in fact the temperature of the British Islands is now in excess above the mean of their latitude by 5°, 10°, 15°, and more, and this excess is merely due to oceanic currents and other conditions which vary with the distribution of land and water.

Notwithstanding the immense accession of snow and ice which the glaciers receive every winter, and which is much greater than what could possibly be thawed by the mere effect of a short summer in the higher Alpine regions, it is found that they have not sensibly increased. If for one or a few years in succession some of the glaciers are observed to descend lower than usual, they are found in the following years to recede proportionably; thus they are confined within certain limits by a compensating process of nature. The evaporation from ice, and particularly from snow, is considerable even in winter, and goes on with great rapidity in a dry and rarefied air; and subterranean heat, as we have already observed, produces throughout the year a certain diminution of the glaciers at their under surface. In the summer the general thawing of all the parts exposed to the direct rays of the sun, to the warm atmosphere, and to the heated soil at the edges of the glaciers, tends greatly to diminish the quantity of ice—an effect increased by the mechanical action of the torrents which this thawing occasions. But all these causes, powerful as they are, would be insufficient to prevent a constant though gradual increase of the ice, were it not for the advance of the glaciers into the warm atmosphere of the lower valleys. The greater the increase of the preceding winter the greater the pressure from above, and the lower the glacier slips into the thawing region. The farther it slips the greater space is left behind to be filled up, and consequently the greater time must elapse before the mass can again be urged forward. During this time the lower extremity, subjected to the heat of two or three summers, recedes as much as or more than it had before advanced; and thus an admirable compensation is established, by which the cultivated lands of the lower valleys are secured against the unlimited encroachments of the glaciers.

The number and extent of the Alpine glaciers is very considerable. From Mont Blanc to the borders of the Tyrol there are reckoned about 400 glaciers, of which a very few are only 3 miles in length; the greater number range from 10 to 15 miles long, and from a mile to 2½ miles broad. The thickness of some of the glaciers is also very considerable, being from 100 to 600 feet.

It is calculated that the glaciers of the Tyrol, Switzerland, Piedmont, and Savoy form together a superficial extent of 1484 square miles. Such are the great reservoirs whence some of the principal rivers of Europe draw their inexhaustible supplies. It is observable that there are but few glaciers in the direction of east and west.

The above account refers chiefly to the glaciers of the Alps; but as all glaciers, wherever they may be, have the same origin, it is presumable they are also subjected to like influences, and present similar phenomena.

The Pyrenean chain, as also the Sierra Nevada, have glaciers, though they are almost all on the northern slopes, there being none on the southern declivities, except in such places as are sheltered from the sun and south wind by other and more advanced mountains. In the mountains of Norway there are several glaciers. Spitzbergen has its eminences covered with snow and surrounded by glaciers.

In Iceland the glaciers are both numerous and extensive; they generally hang on the rapid slopes of the mountains, and sometimes wholly encase them. These ice-clad elevations are termed Jokūls, the principal of which is that named Klofa Jokūl, in the eastern quarter of the island, and which, according to Henderson, forms, with little or no interruption, a vast chain of ice and snow mountains not less than 3000 miles square. Another, called Blafell's Jokūl, extends from near Tindafiall 100 miles across the island in a westerly and northerly direction, and near the Lake Hvitârvatn presents the most magnificent glaciers. There are numerous other glaciers; many of them, besides the usual phenomena, exhibiting marks of the extraordinary convulsions occasioned by volcanic action and the emission of hot water from the sides of the mountains.

Greenland, as far as is known, contains innumerable glaciers, many of great thickness; and the inhabitants of both the east and west coast are persuaded of their continual increase. It is remarkable that although Graah, in his account of Greenland, describes the glaciers as formed in the same manner with those of the Alps, yet he and all travellers notice the beautiful transparency and consequent compactness of the northern glaciers, and of the icebergs which have been detached from them; a circumstance which seems to denote some peculiar modification of the process of their formation.

Along the south-west coast of South America there are extensive glaciers, as also in the Strait of Magalhaens, and in Tierra del Fuego.

In the Himalayas glaciers have been observed, and all the phenomena presented in Europe have also been found there.

GLADIOLUS, Corn-Flag (from 'gladius,' a sword, referring to the shape of the leaves), a genus of Plants belonging to the natural order *Iridaceæ*. It has a tubular 2-lipped corolla; segments undulate and unequal; stigma trifid; seeds with an arillus; root a coated bulb; leaves ensiform, sheathing. The species in the gardens are bulbous, and are chiefly brought from the Cape of Good Hope.

G. segetum has about 10 flowers in two rows. The upper division of the corolla is divaricate, the lower segment nearly equal and lanceolate; anthers longer than the filaments; capsules with 3 furrows. It has been supposed to be an aphrodisiac, a reputation obtained from its acrid qualities, which are however common to the whole of the order. The Hottentots eat the tubers or corms of several species of this genus, the starch they contain rendering them nutritious.

G. triphyllus has about 3 flowers in one row; the anthers much shorter than the filaments. It is found in the mountains of Carrara.

G. palustris has 3 or 4 flowers, secund; the tube twice as long as the seed-vessel; the claw of the middle division curved and remote; the lobes of the stigma papilloso-ciliate almost from the base; anthers shorter than the filaments; auricles at the base obtuse, parallel; capsules oblong, obovate, rounded at the top, marked with six equal furrows. It is found in Germany.

G. communis has secund flowers; the filaments half as long again as the anthers; auricles at the base obtuse and parallel; the tube half as long again as the germen; lobes of the stigma gradually broader upwards, papilloso-ciliate almost from the base; capsules 3-edged, obovate, impressed at the top; the seeds broadly winged. It is found near Stettin and Frankfurt-on-Oder.

G. Illyricus has secund flowers; the tube three times as long as the germen; division of stigma linear from the base to the middle, and with a smooth margin suddenly enlarged at the top with a papilloso-ciliate margin; the capsules obovate, 3-edged. A native of Illyria.

G. imbricatus has secund approximate flowers; the tube nearly three times as long as the germen; the division of stigma gradually broader upwards, papilloso-ciliate almost from the base; the capsules with 3 rounded angles. Found in Bohemia and Silesia.

G. infestus has a lax spike; flowers 4 to 14, obliquely alternate; division of corolla alternately pink and purple, uppermost very broad, covering the 2 lateral ones, the 3 lower unequal; anthers about as long as the filaments; seeds globose, prolonged downwards. It is a native of Sicily.

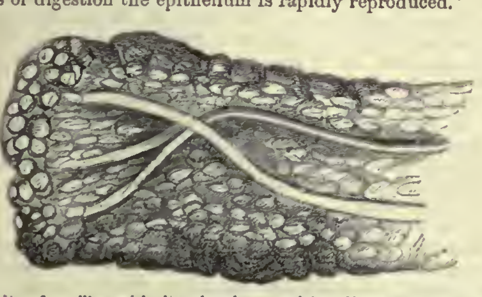
G. Byzantinus has numerous flowers in two rows; the upper segment of the corolla covered by the lateral ones; the lower division lanceolate, the middle largest; the anthers longer than the filaments; seeds winged; leaves long, ensiform, and linear. Found in Sicily.

GLAND, a term applied to cells and collections of cells in the animal body, which have the power of absorbing or separating the various substances which pass into or are separated from the circulating fluid. In one sense all the cells of the animal act as glands, for they separate from the blood the peculiar substances of which they are composed. The term gland however is only strictly applied to special forms of tissue which separate peculiar matters. "A true gland," says Dr. Carpenter, "may be said to consist of a closely packed collection of follicles, all of which open into a common channel, by which the product of the glandular action is collected and delivered. The follicles contain the secreting cells in their cavities, whilst their exterior is in contact with a network of bloodvessels from which the cells draw the materials of their growth and development."

In a wider sense however the term gland has been applied to those parts of the body which are engaged in absorbing the food or carrying to the blood the materials of used-up tissues. [ABSORBENT SYSTEM; ABSORPTION]. In all cases the cell is an active agent whether of absorption or separation. The agency of the cell in absorption is seen in the way in which the chyle is taken from the intestines and carried into the lacteals.

Professor Goodsir has recently shown that there is a continual development of cells at the extremity of each villus in the small intestine, and that these cells are the agents by which the secretion of the nutritious fluid is accomplished, and by which it undergoes its first preparation for the purposes it is subsequently to fulfil. The nature of this process we give in Professor Goodsir's own words, omitting those portions which do not bear specially on the point.

"As the chyle begins to pass along the small intestine, an increased quantity of blood circulates in the capillaries of the gut. In consequence of this increased flow of blood, or from some other cause with which I am not yet acquainted, the internal surface of the gut throws off its epithelium, which is intermixed with the chyme in the cavity of the gut. The cast-off epithelium is of two kinds,—that which covers the villi, and which, from the duty it performs, may be named protective epithelium; and that which lines the follicles, and is endowed with secreting functions. The same action then, which in removing the protective epithelia from the villi prepares the latter for their peculiar function of absorption, throws out the secreting epithelia from the follicles, and thus conduces towards the performance of the function of these follicles. The villi, being now turgid with blood, erected, and naked, are covered or coated by the whitish-gray matter already described. This matter consists of chyme, of cast-off epithelia of the villi, and of the secreting epithelia of the follicles. The function of the villi now commences. The minute vesicles which are interspersed among the terminal loops of the lacteals of the villus, increase in size by drawing materials from the blood through the coats of the capillary vessels, which ramify at this spot in great abundance. While this increase in their capacity is in progress, the growing vesicles are continually exerting their absorbing function, and draw into their cavities that portion of the chyme in the gut necessary to supply materials for the chyle. When the vesicles respectively attain in succession their specific size, they burst or dissolve, their contents being cast into the texture of the villus, as in the case of any other species of interstitial cell. The débris, and the contents of the dissolved chyle-cells, as well as the other matters which have already subserved the nutrition of the villus, pass into the looped network of lacteals, which, like other lymphatics, are continually employed in this peculiar function. As long as the cavity of the gut contains chyme, the vesicles of the terminal extremity of the villi continue to develop, to absorb chyle, and to burst, and their remains and contents to be removed along the lacteals. When the gut contains no more chyme, the flow of blood to the mucous membrane diminishes, the development of new vesicles ceases, the lacteals empty themselves, and the villi become flaccid. The function of the villi now ceases till they are again roused into action by another flow of chyme along the gut. During the intervals of absorption, it becomes necessary to protect the villi from the matters contained in the bowel. They had thrown off their protective epithelium when required to perform their functions, just as the stomach had done to afford gastric juice, and the intestinal follicles to supply their peculiar secretions. In the intervals of digestion the epithelium is rapidly reproduced."



Extremity of a villus with its absorbent vesicles distended with chyle, and the trunks of its lacteals seen through its coats. Very highly magnified.

The researches of Professor Goodsir have likewise thrown much light on the general process of secretion. He shows, by an admirably selected series of observations (chiefly on the lower animals), that secretion is a function of the nucleated cell.

If the membrane which lines the secreting portion of the internal surface of the ink-bag of *Loligo sagittata* (Lamarck) be carefully freed from adhering secretion by washing, it will be found to consist almost entirely of nucleated cells, of a dark brown or black colour. These cells are spherical or ovidal. Their nuclei consist of cells grouped together in a mass. Between these composite nuclei and the walls of their containing cells is a fluid of a dark brown colour. This fluid resembles in every respect the secretion of the ink-bag itself. It renders each cell prominent and turgid, and is the cause of its dark colour.

The dilated terminal extremities of the ducts in the liver of *Helix aspersa* (Müller) contain a mass of cells. If one of these cells be isolated and examined, it presents a nucleus consisting of one or more cells. Between the nucleus and the wall of the containing cell is a fluid of an amber tint, and floating in this fluid are a few oil-globules. This fluid differs in no respect from the bile as found in the ducts of the gland. The liver of *Modiola vulgaris* (Fleming) contains masses of spherical cells. Between the nucleus and the wall of each of these cells a light-brown fluid is situated, bearing a close resemblance to the bile in the gastro-hepatic pouches. The nucleated cells which are arranged around the gastro-hepatic pouches of *Pecten opercularis* are irregular in shape, and distended with a fluid resembling the bile. The hepatic organ which is situated in the loop of intestine of *Pirena prunum* (Fleming) consists of a mass of nucleated cells. These cells are collected in groups in the interior of larger cells or vesicles. These nucleated cells are filled with a light-brown bilious fluid. The hepatic organ situated in the midst of the reproductive apparatus, and in the loop of the intestine of *Phallusia vulgaris* (Forbes and Goodsir), consists of a number of vesicles, and each vesicle contains a dark-brown bilious fluid.

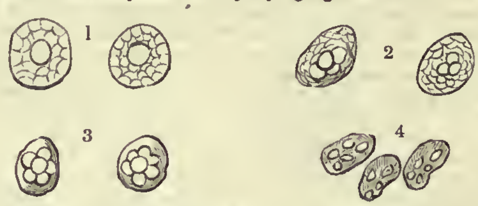
The hepatic cæca in the liver of *Patella vulgata* contains vesicles inclosing a body which consists of a number of nucleated cells full of a dark fluid resembling the bile. The kidney of *Helix aspersa* (Müller) is principally composed of numerous transparent vesicles. In the centre of each vesicle is situated a cell full of a dead white granular mass. This gland secretes pure uric acid. The ultimate elements of the human liver are nucleated cells. Between the nucleus and the cell-wall is a light brown fluid with one or two oil globules floating in it. The vesicular cæca in the testicle of *Squalus cornubicus* contain nucleated cells, which ultimately exhibit in their interior bundles of spermatozoa. The generative cæca of *Echiurus vulgaris* (Lamarck) contain cells full of minute spermatozoa. *Aplysia punctata* secretes from the edge and internal surface of its mantle a quantity of purple fluid. The secreting surface of the mantle consists of an arrangement of spherical nucleated cells. These cells are distended with a dark purple matter. The edge and internal surface of the mantle of the *Janthina fragilis* (Lamarck), one of the animals which supplied the Tyrian dye, secretes a deep bluish-purple fluid. The secreting surface consists of a layer of nucleated cells, distended with a dark purple matter. If an ultimate acinus of the mammary gland of the bitch he examined during lactation it is seen to contain a mass of nucleated cells. These cells are generally ovoidal, and rather transparent. Between the nucleus and the cell-wall of each a quantity of fluid is contained, and in this fluid float one, two, three, or more oil-like globules, exactly resembling those of the milk.

The secretion within a primitive cell is always situated between the nucleus and the cell-wall, and would appear to be a product of the nucleus.

The ultimate secreting structure then is the primitive cell, endowed with a peculiar organic agency, according to the secretion it is destined to produce. Mr. Goodsir names it the primary secreting cell. It consists, like other primitive cells, of three parts—the nucleus, the cell-wall, and the cavity. The nucleus is its generative organ, and may or may not, according to circumstances, become developed into young cells. The cavity is the receptacle in which the secretion is retained till the quantity has reached its proper limits, and till the period has arrived for its discharge. Each primary secreting cell is endowed with its own peculiar property, according to the organ in which it is situated. In the liver, it secretes bile; in the mamma, milk, &c. The primary secreting cells of some glands have merely to separate from the nutritive medium a greater or less number of matters already existing in it. Other primary secreting cells are endowed with the more exalted property of elaborating from the nutritive medium matters which do not exist in it. The discovery of the secreting agency of the primitive cell does not remove the principal mystery in which this function has always been involved. One cell secretes bile, another milk; yet the one cell does not differ more in structure from the other than the lining membrane of the duct of one gland from the lining membrane of the duct of another. The general fact however that the primitive cell is the ultimate secreting structure is of great value in physiological science, inasmuch as it connects secretion with growth, as phenomena regulated by the same laws. The force, of whatever kind it may be, which enables one primary formative cell to produce nerve and another muscle, by an arrangement within itself of the common materials of nutrition, is identical with that force which enables one primary secreting cell to distend itself with bile and another with milk.

Instead of growth being a species of imbibing force, and secretion on the contrary, a repulsive, the one centripetal, the other centrifugal, they are both centripetal. Even in their latter stages the two processes, growth and secretion, do not differ. The primary formative cell after becoming distended with its peculiar nutritive matter, in some instances changes its form according to certain laws; and then, after a longer or shorter period, dissolves and disappears in the intercellular space in which it is situated; its materials passing into the circulating system if it be an internal cell, and being merely thrown off if it be an external cell. The primary secreting cell, again, after distension with its secretion does not change its form so much as certain of the formative cells, but the subsequent stages are identical with those of the latter. It bursts or dissolves, and throws out its contents either into ducts or gland-cavities.

The general fact of every secretion being formed within cells explains a difficulty which has hitherto puzzled physiologists, namely, why a secretion should only be poured out on the free surface of a gland-duct, or secreting membrane. We have attempted to illustrate Mr. Goodsir's views by the accompanying figures :—



1. Cells from the kidney of *Helix aspersa*. The contained secretion is dead-white and presents a chalky appearance.
2. Cells from the ink-bag of *Loligo sagitta*.
3. Cells from the liver of the *Patella vulgata*. In this instance the bile is contained in the cavities of the secondary cells, which constitute the nucleus of the primary cell.
4. Cells from the mamma of a bitch. In addition to their nuclei these cells contain milk-globules.

After describing the development of glandular tissue Professor Goodsir concludes his paper on this subject with the following remarks :—

"It appears to be highly probable therefore that a gland is originally a mass of nucleated cells, the progeny of one or more parent cells; that the membrane in connection with the embryo gland may or may not, according to the case, send a portion of the membrane in the form of a hollow cone into the mass; but whether this happens or not, the extremities of the ducts are formed as closed vesicles, and then nucleated cells are formed within them, and are the parents of the epithelium cells of the perfect organ. Dr. Allen Thomson has ascertained that the follicles of the stomach and large intestines are originally closed vesicles. This would appear to show that a nucleated cell is the original form of a follicle, and the source of the germinal spot, which plays so important a part in its future actions. The ducts of glands are therefore intercellular passages. This is an important consideration, inasmuch as it ranges them in the same category with the intercellular passages and secreting receptacles of vegetables.

"Since the publication of my paper on the secreting structures, in the 'Transactions of the Royal Society of Edinburgh,' in 1842, I have satisfied myself that I was in error in attributing to the cell-wall the important function of separating and preparing the secretion contained in the cell-cavity. The nucleus is the part which effects this.

The secretion contained in the cavity of the cell appears to be the product of the solution of successive developments of the nucleus, which in some instances contains in its component vesicles the peculiar secretion, as in the bile-cells of certain *Mollusca*; and in others becomes developed into the secretion itself, as in seminal cells. In every instance the nucleus is directed towards the source of nutritive matter; the cell-wall is opposed to the cavity into which the secretion is cast. This accords with that most important observation of Dr. Martin Barry on the function of the nucleus in cellular development. I have also had an opportunity of verifying—and to an extent which I did not at the time fully anticipate—the remarkable vital properties of the third order of secretion referred to in the memoir to which I have just alluded. The distinctive character of secretions of the third order is, that when thrown into the cavity of the gland they consist of entire cells, instead of being the result of partial or entire dissolution of the secreting cells. It is the most remarkable peculiarity of this order of secretions, that, after the secreting cells have been separated from the gland and cast into the duct, or cavity, and therefore no longer a component part of the organism, they retain so much individuality of life as to proceed in their development to a greater or less extent in their course along the canal or duct before they arrive at their full extent of elimination. The most remarkable instance of this peculiarity of secretions of this order is that discovered by my brother. He has observed that the seminal secretion of the decapodous crustaceans undergoes successive developments in its progress down the duct of the testis, but that it only becomes developed into spermatozoa after coitus, and in the spermatheca of the female. He has also ascertained that, apparently for the nourishment of the component cells of a secretion of this kind, a quantity of albuminous matter floats among them, by absorbing which they derive materials for development after separation from the walls of the gland. This albuminous matter he compares to the substance which, according to Dr. Martin Barry's researches, results from the solution of certain cells of a brood, and affords nourishment to their survivors. It is one of other instances in which cells do not derive their nourishment from the blood but from parts in their neighbourhood which have undergone solution, and it involves a principle which serves to explain many processes in health and disease.

"I conclude therefore, from the observations which I have made, 1st, that all the true secretions are formed or secreted by a vital action of the nucleated cell, and that they are first contained in the cavity of that cell; 2nd, that growth and secretion are identical—the same vital process under different circumstances."

Having thus examined the nature of the process by which the cell secretes, we may now refer to some of the more prominent modifications of the organs called glands. The simplest condition of a Gland is the simple inversion of a secreting membrane called a follicle. These occur in the skin, as in the sebaceous follicles, and also in the mucous membrane of the stomach, where they are called gastric follicles. In these cases we have simply a pit in the membrane covered with secreting cells. In the early stages of the development of all glands we have this simple condition, and in the permanent condition of the more complicated glands, when occurring in the lower animals, we have the same simple development. Thus the liver in some of the Polypes and lower *Mollusca* consists merely of a series of separate follicles placed in the walls of the stomach. The chick whilst in the egg presents the same condition of this organ. The same simplicity is seen in the commencement of the development of a mammary gland in the *Mammalia*. In the *Ornithorhynchus* this organ consists of a mere cluster of blind sacs. In the same way in many fishes the pancreas begins its existence as a mere group of blind follicles. The next stage in the complexity of a gland is where a number of follicles open into a single tube. Such a condition of the gland is seen in what are called the Meibomian glands of the eye. The larger glands of the body, as the pancreas, liver, and parotid gland, are but mere complicated stages of this process. Innumerable follicles empty themselves into tubes which again empty themselves into other tubes until the whole contents of the gland are thrown out from some common outlet.

For further information on the subject of the Glandular System see LIVER; PANCREAS; BILE; PAROTID; DIGESTION; SECRETION; ABSORBENT SYSTEM; SALIVA; KIDNEYS; URINE; SKIN.

GLAPHYRIA, a genus of Plants belonging to the natural order *Myrtaceæ*. The limb of the calyx is 5-lobed, petals 5, berry 5-celled, many seeded; seeds fixed to the axis, 2 rows in each cell. The species are small Indian trees, with alternate minutely-stipitate leaves, and few-flowered axillary peduncles.

G. nitida is called by the Malays 'the Tree of Long Life,' probably from its maintaining itself at elevations where the other denizens of the forest have ceased to exist. It affords at Bencoolen a substitute for tea, and is known by the name of the Tea Plant. Various species of *Leptospermum* and *Melaleuca* bear the same name in the Australian colonies.

G. sericea has lanceolate acuminated leaves. It is a native of Pulo Penang and on the west coast of Sumatra. The calyx, peduncles, bracts, and young leaves are silky; the petals and cells of ovarium 5 or 6 in number.

GLAREOLA. [CHARADRIADÆ.]

GLASSWORT. [SALICORNIA.]

GLAUBER SALT, native Sulphate of Soda. It is monoclinate, and occurs in oblique rhombic prisms. It is found in efflorescent crusts, of a white or yellowish-white colour, also in mineral waters. Its taste is cool, saline, and bitter. It is distinguished from Epsom salt by its coarse crystals and the yellow colour it gives to the blowpipe flame. The artificial salt was first discovered by Glauber, a German chemist. It is found in sea-water, and is obtained from this source for use in medicine and the arts. At Kailua, in Hawaii, one of the Sandwich Islands, it is found abundantly in a cave, where it is constantly forming. It is also found in Austria and Hungary, and the United States of America.

GLAUBERITE, a native Sulphate of Lime and Soda. It occurs in oblique crystals, which are usually flattened, with sharp edges; nearly transparent, and yellowish-gray in colour. The taste is weak, and slightly saline. It is found in rock-salt at Villa Rubia in Spain, at Aussee in Upper Austria, and Vic in France.

GLAUCIUM (from γλαυκός, 'sea-green, or glaucous,' in allusion to the colour of the plant and its habitation by the sea-side), a genus of Plants belonging to the natural order *Papaveraceæ*. It has 2 sepals, 4 petals, and indefinite stamens; elongated 2-valved capsules, a bilamellate stigma, and ovate reniform seeds. The species are evergreen glaucous biennial or annual herbs, abounding in a copper-coloured acrid juice, said to be poisonous and to occasion madness. The flowers are yellow or crimson; and the English name of the genus, Horn-Poppy, originates in the horn-like shape of the pods.

G. luteum, Yellow Horn-Poppy, has a smooth stem and a tubercular scabrous pod. The flowers are large, and of a golden-yellow colour. It is found on the sandy sea-shores of Great Britain, and also in the Carolinas and Virginia. It is the μήκων κερατῖτις of Theophrastus ('Hist. Plant.,' 9, 13).

G. phœniceum is regarded by De Candolle as a variety of *G. corniculatum*. It is a native of the south of Europe, and is occasionally found on the coast of England. It is however considered by Babington to be a doubtful native. The flowers are crimson, and have an elegant appearance. Don enumerates six species of *Glaucium*, none of which however are applied to any useful purposes. The species of Horn-Poppy thrive well in any common garden-soil, and may be easily raised from seeds, which ripen in great abundance.

(Don, *Dichlamydeous Plants*; Babington, *Man. Brit. Bot.*)

GLAUCOLITE. [LABRADORITE.]

GLAUCONIE, a French term used principally by M. Brongniart, to signify some stratified deposits associated with the chalk, which correspond to the greensands of English geologists. The Glauconie Crayeuse is considered by M. Brongniart to be the equivalent of the upper greensand, and the Glauconie Sableuse of the lower greensand. The same author uses the term Glauconie Grossière for a deposit above the chalk.

GLAUCONOME (*Glauconome*, Nereidis filia), is used to denote a genus established by Goldfuss, for species of Celluliferous *Polyparia* found in the chalk of Westphalia.

Glauconome is also the name of a fresh-water genus of conchifers of the family *Veneridæ*, established by Dr. Gray in his 'Spicilegia Zoologica.' [VENERIDÆ.]

GLAUCO'PIS, a genus of Birds established by Forster (*Calæas* of Bechstein and Vieillot), belonging to the order *Insessores*.

It has the following generic character:—Bill moderate, strong, robust, thick, with the base enlarged towards the commissure; upper mandible convex, vaulted, curved towards the end, and without any notch; lower mandible following the curvature of the upper, straight below, hidden in part by the sides of the upper mandible. Nostrils basal, lateral, round, partially closed by a large membrane, and entirely hidden by the curled and velvetty feathers which advance from the forehead. Feet strong, robust; tarsi longer than the middle toe; toes nearly all of a length, the external toe united to the middle one, and the internal toe soldered (soudé) at the base. Wings short; the first quill short, the three following graduated, and the fifth longest. Tail long, graduated. (Temminck.) The above character is adopted in Lesson's 'Manuel,' and the following three species are there arranged under the genus, namely, *G. cinerea*, *G. leucoptera*, and *G. Temnura*.

M. Temminck describes *G. Temnura* as one-third larger than *G. Temia* (*Corvus varians* of authors), or the Pie Temia of Le Vaillant's 'Birds of Africa.' He observes that the striking character in *G. Temnura* consists in a very graduated tail (queue très étagée), all the feathers of which are truncated and cut, as it were, transversely at their extremity. The whole of the plumage is black, a little lustrous on the wings and tail. Bill and feet black. Total length 12 inches. It is found in Cochin China. M. Lesson observes that this species will form a new genus.

In Mr. Swainson's 'Classification of Birds,' vol. ii., part 4, *G. Temnura* is referred to *Crypsirina*, and the following generic character is given by him: some of the characters, not inserted in his own notes, rest on the authority of the 'Manuel d'Ornithologie.'

Glaucopis (Forster). Bill short, strong, robust; the culmen elevated and curved from the base; upper mandible destitute of a notch; under mandible straight (on the gonys), the margin covered by that of the upper and furnished at the base with two fleshy wattles.

Nostrils basal, lateral, partly closed by a large membrane. Feet very strong, formed for walking. The tarsus longer than the middle toe; lateral toes short, of equal length, and divided to their base; hind toe strong, armed with a long curved claw. Wings short. Tail rather lengthened, rounded; the feathers ending in setaceous points.

Glaucopis Temnura. (Temm.)

In the third part of the 'Classification of Birds,' in the same vol., Mr. Swainson states that the *Glaucopinæ*, or Rasorial Crows, form the only division of the family which he had then analysed with a view to determine its chief generic types. As a whole he thinks that they are distinguished from all other birds by their short finch-like bill, the commissure of which is always arched, and sometimes sinuated like that of a *Fringilla*. The genus *Glaucopis*, which he considers the pre-eminent type, shows this structure, in his opinion, in great perfection, "added to another which is equally indicative of the rasorial structure, that is, strong walking legs. Following this we have the Senegal Piapec, forming our genus *Ptilostomus*, intimately related, according to M. Temminck, with his *Corvus gymnocephalus*." [Corvidæ.] "Upon this authority we conjecture the last-mentioned bird may prove the grallatorial type. The singular genus *Brachystoma*, from New Holland, long since noticed by us as connecting this bird with the jays, leads at once to the Finch Crows of India, all of which, in our opinion, are merely variations of that type named *Crypsirina* by M. Vieillot. Some of these, from their close resemblance to *Glaucopis*, have actually been placed in that genus by M. Temminck, who seems to have overlooked the entirely different structure of their legs. The circle is thus closed, and we find that these five types represent the primary divisions of the whole class."

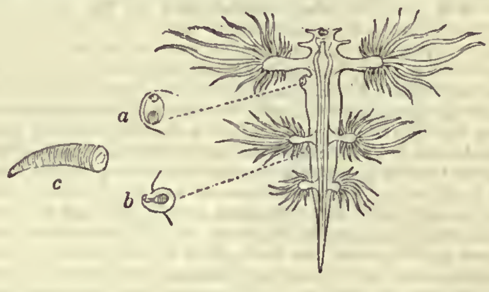
The following are Mr. Swainson's views of the position of the *Corvidæ*:—He is of opinion that the *Corvidæ* are nearest allied to the Hornbills, although the intervening forms are few. The genus *Frigillus* (*Fregilus*?) is the only representative he at present knows of that sub-family which intervenes between the *Buceridæ* and the *Corvinæ*. He observes that the whole family has never yet been analysed, so that the leading divisions alone can yet be made out or stated with any degree of certainty; and says that the little value which can be attached to speculations on the rank of the present genera, founded upon mere synthesis, will best appear by looking to those artificial arrangements that place short-legged Rollers close to the long-legged and powerfully constructed Grakle (*Gracula religiosa*), two genera moreover which analysis has convinced him do not belong to this family. "Nothing in short," continues Mr. Swainson, "is more easy than to divide a group like this into three, five, seven, or any other given number; but the divisions must always be considered as temporary, until confirmed by analysis. We have not yet carried our investigations so far as to lay before the reader an arrangement of all the genera of this family; nor will our space admit of an attempt to demonstrate those groups in it which we have already marked out. We shall therefore merely intimate what we conceive to be the only natural series, by arranging the genera, in our synopsis, under the following sub-families:—1, *Frigillinæ* (*Fregilinæ*?); 2, *Corvinæ*; 3, *Garrulinæ*; 4, *Crypsirinæ*; and 5, *Coracinæ*."

He excludes from the family *Epimachus*, as belonging to the Suctorial Birds; *Coracias*, as being completely united to *Eurystomus* by two species; and *Gracula*, as united to *Pastor* among the *Sturnidæ*. The Paradise Birds, hitherto arranged with the Crows, form, in his opinion, the most aberrant group of his *Tenuirostres*, and one placed between the Hoopoes and the Honey-Suckers. From the Crows he proceeds to the Starlings (*Sturnidæ*).

In the 'Synopsis of a Natural Arrangement of Birds' (part iv. of the same vol.), Mr. Swainson observes that "there are a few alterations in the arrangement of the groups from what they appear in the foregoing part: this has resulted from further analysis, and by incorporating our researches up to the latest time." We here find the *Corvidæ* thus arranged: Sub-family *Corvinæ*, Typical Crows—*Corvus*, *Pica*, *Nucifraga*, *Barita*, *Vanga*, *Platylophus*, *Phonygama*. Sub-family *Garrulinæ*, Jays—*Garrulus*, *Cyanurus*, *Dysornithia*. Sub-family *Glaucopinæ*, Wattle Crows—*Crypsirina*, *Ptilostomus*, *Brachystoma*, *Glaucopis*. Sub-family *Coracinæ*, Fruit Crows—*Coracina*, *Cephalopterus*, *Gymnocephalus*. Sub-family *Frigillinæ* (*Fregilinæ*?) which, he remarks, contains at present but two European birds (*F. Pyrrhocorax* and *F. erythropus*), which almost appear to be types of as many genera. The characters which he gives are, he observes, more strictly applicable to the first. [Corvidæ; Coracina.]

GLAUCUS, a genus of Molluscous Animals named by Forster, and placed by Cuvier among his *Nudibranchiata*; by De Blainville under his *Polybranchiata* (Family *Tetracerata*); and by Rang made the type of a family, Les Glauques (*Glaucidæ*), which together with *Glaucus* comprises the genera *Laniogerus*, De Blainville; *Briaræa*, Quoy and Gaimard; *Eolidia*, Cuvier; *Cavolina*, Bruguières; and *Tergipes*, Cuvier.

It has the following generic characters:—Animal gelatinous, elongated, slightly flattened, and terminated backwards in a point. Foot very narrow and almost rudimentary. Head distinct, furnished with four very short flattened and triangular tentacula; the mouth subterminal. Branchiæ disposed in pairs on the sides, and fitted for swimming, being formed by oblong processes (palettes oblongues) surrounded by digitated appendages. Termination of the organs of generation in a common tube at the anterior part of the right side; vent on the same side, more backwards. (Rang.)



Glaucus.

a, common tubercle of the organs of generation; *b*, vent; *c*, one of the digitations magnified. (De Blainville.) *a* would represent the anus, according to Mr. Bennett.

Deshayes, in his edition of Lamarck (who made *Glaucus* the first genus of his family Tritonians), remarks, that, notwithstanding the researches of several accomplished naturalists, there still exists uncertainty as to many points of the anatomy of this genus. The description of M. De Blainville, he observes, leaves doubts concerning the organs of respiration; nor is it, he adds, certain that the digitations of the fins are branchiæ: in the opinion of M. Deshayes they are not. M. Quoy, he continues, says that these digitations are very caducous in the living animal, which detaches them when they are touched; and it is not to be believed that this would take place if these parts were destined for so important a function as that of respiration. M. Deshayes therefore points out the necessity of new researches as to the organisation of these animals. The same zoologist states that the majority of naturalists are now convinced that as yet but one species is known; and he adds, that it must be confessed that the figures given are very inexact, with the exception of that given by Messrs. Quoy and Gaimard ('Voy. de l'Astr.,' Zool. t. 2, pl. 21, f. 6 to 14), which conveys a good idea of this elegant animal.

Mr. G. Bennett states that during a voyage from England to Sydney, in 4° 26′ N. lat., 19° 30′ W. long., with light airs and calms prevailing at the time, a number of damaged and perfect specimens of the *Glaucus hexapterygius* (Cuvier), were caught in the towing-net, and placed in a glass of sea-water, where they resumed their vital actions and floated about, exhibiting a brilliancy of colour and peculiarity of form that excited admiration. The back of the animal, as well as the upper surface of the fins and digitated processes, and the upper portion of the head and tail, were of a vivid purple colour, varying occasionally in its intensity, appearing brighter in colour when the animal was active or excited, and deeper when it remained floating tranquilly upon the surface of the water. The abdomen and under surface of the fins were of a beautiful pearly white colour, appearing as if it had been enamelled. The usual length of Mr. Bennett's specimens, measured from the extremity of the head to the tail, when extended floating upon the surface of the water, was one inch and three-quarters, sometimes one or two lines more or less. Mr. Bennett describes the body of the animal as subcylindrical, terminating in a tail, which gradually becomes more slender towards the extremity until it finally terminates in a delicate point; the head is short, with very small conical tentacula in pairs, two superior and two inferior; three (and in *G. octopterygius*, Cuvier, four) branchial fins on each side, opposite, palmated, and digitated at their extremities, the number of digitations varying, the central digitations being the longest, and the first branchial fins, or those nearest the head, larger and more dense than the others. The body is gelatinous, and covered, he says, by a thin and extremely sensible membrane. "When taken in the hand," continues Mr. Bennett, "the under surface of the animal soon becomes denuded of the beautiful pearly white it previously had, and at that time appears like a small transparent bladder, in which a number of air-bubbles are observed together with the viscera. On the abdomen being laid open a large quantity of air-bubbles escaped; and perhaps a query may arise how far they assist the animal in floating upon the surface of the water. The figure of *Glaucus hexapterygius* in Cuvier's work 'Sur les Mollusques' is tolerably well executed, but no engraving can convey to the beholder the inconceivable delicacy and beauty of this mollusk. In the engraving alluded to there is an inaccuracy, at least as compared with the specimens before me, in the digitated processes of the fins not being sufficiently united at the base: in the living specimens before me they were united together at the base, and then branching off became gradually smaller until they terminated in a fine point. Again, in the engraving in Cuvier's work the anal orifice is placed on the right side, whereas in my specimens it was situated on the left; for in all the specimens I examined I found the anus was disposed laterally, and could be plainly distinguished situated on the left side of the animal, a little below the first fin. This I consider also the orifice of generation, as in some of the specimens examined a rather long string of dots resembling ova was seen to protrude from it. One of the animals discharged from this orifice a large quantity of very light brownish fluid; this no doubt was the fæces."

Numbers of the same species were taken by the same zoologist towards the end of the same month in 2° 26′ N. lat., 19° 51′ W. long., light airs, nearly calm. Often when at rest the animal would drop one or more of the fins, but on touching them they would be immediately raised to their former position, and the fin was turned back as if to throw off the offending object. From Mr. Bennett's observations It appears that the *Glauci* actually feed upon *Porpitæ*, and probably upon *Velellæ* and *Janthinæ;* that the animal shows more sensitiveness on the back than it does when touched elsewhere; that it does not seem to be disturbed by the contact of another *Glaucus;* that the fins have an undulating and a twisting movement; and that a circulating fluid could be perceived by means of a glass through the semi-transparent membrane of the back, close to the surface, flowing in two directions—one taking a course downwards and the other upwards. It appears moreover, from the testimony of Mr. Bennett and others, that no means have yet been discovered for preserving these evanescent creatures, which lose their beauty and form even when taken alive out of the water and laid upon the hand. "The digitations of the fins fell off, the least movement destroyed the beauty of the animal; it speedily lost all the deep purple and silvery enamelled tints, and became a loathsome mass." ('Zoological Proceedings,' 1836.) Spirit, it is to be feared, would never preserve them in a state available for examination. We mention this to induce those observers who may have the opportunity, to follow out their researches on the animal's organisation, by watching it narrowly with good glasses whilst it is alive.

GLAUX, a genus of Plants belonging to the natural order *Primulaceæ*. It has a bell-shaped calyx, 5-parted, coloured, and without any corolla, by which peculiarity it is distinguished from all other plants of the same order. There are 5 stamens inserted at the base of the calyx; the capsules are few-seeded, opening with 5 valves. There is but one species of this genus.

G. maritima, the Black Saltwort, has a procumbent stem, opposite ovate glabrous leaves, axillary sessile pink flowers with obtuse segments. It grows on the sea-shore and salt-marshes, and is a native of Great Britain.

(Babington, *Manual of British Botany*.)

GLEAD. [FALCONIDÆ.]

GLECHOMA. [NEPETA.]

GLEDITSCHIA, a genus of Plants named in honour of Gottlieb Gleditsch, a professor at Berlin, and author of a work on the sexual system of Linnæus entitled 'Consideratio epicriseos Siegesbeckianae in Linnaei systema plantarum sexuale et methodum botanicam.' (Bischoff, p. 562.) He was a good botanist, and contributed a valuable paper on the reproductive organs of the *Fungi* to the 'Transactions of the Berlin Academy' in 1748. This genus belongs to the natural order *Leguminosæ* and the sub-order *Cassieæ*. The flowers are unisexual, the calyx has 3-4-5 equal sepals, which are connected together at the base into a cupule. The petals are equal in number to the sepals; two of them are connected into a carina. The leaves are abruptly pinnate and bipinnate on the same tree. The flowers have a greenish colour, and are disposed in spikes.

G. triacanthos, the Three-Horned Acacia or Honey Locust, is a large tree, native of the Carolinas and Virginia, and attaining a height of from 50 to 80 feet. When the tree is young, the trunk and branches are covered with small prickles, which become hard as it increases in age, and form a formidable defence. The foliage is of a light shining green, and is particularly elegant. In the neighbourhood of London the leaves do not appear until late in the spring, and drop off early in the autumn. The seeds are covered with a sweet pulp, which, when infused and fermented, forms an intoxicating liquor which was used by the American Indians.

G. monosperma, the One-Seeded Gleditschia, is a native of the Carolinas, Florida, and Illinois, in damp woods. It attains a height of from 60 to 80 feet, and much resembles the former species. When none of the seeds ripen it is impossible to distinguish them. There are 8 species of *Gleditschia* enumerated, all of which possess the same general characters. As ornamental trees they are much esteemed, both on account of their elegant foliage and the varied and picturesque forms assumed by the tree, together with the singular appearance of the spines. They require a deep rich soil in a situation not exposed to high winds.

(Loudon, *Encyclopædia of Trees and Shrubs;* Don, *Dichlamydeous Plants.*)

GLEICHENIACEÆ, an order of Plants constituted by Von Martius, and forming part of Lindley's alliance *Filicales* in the 'Natural System.' In the 'Vegetable Kingdom' it is reduced to the rank of a tribe under the order *Polypodiaceæ*, and with the name *Gleicheneæ*. The species have the following characters:—Spore-cases dorsal with a transverse occasionally oblique ring, nearly sessile, and bursting lengthwise internally; the spores oblong or kidney-shaped. It includes the genera *Gleichenia*, *Mertensia*, *Sticherus*, *Platyzoma*, *Calymella*.

GLENOTREMITES (γλήνη, articular cavity, τρῆμα, a perforation), a genus of *Echinodermata*, with only one opening in the crust; established by Goldfuss, and by him compared to *Cidarites;* found in the chalk of Westphalia. ('Petrifacta Germaniæ.')

GLIRES, the fourth order of *Mammalia* in the 'Systema Naturæ' of Linnæus, who thus characterises it:—Incisors (dentes primores incisores) two above and below; Canines (laniarii) none. Feet unguiculate; progression salient (cursu salientes). Food obtained by gnawing the bark of trees, roots, vegetables, &c. This is the character given in the 'Synopsis' of the *Mammalia*. In the course of the work the dental formula is thus stated:—Incisors (dentes primores), two (bini) above and below, approximate, remote from the molars; no laniarii. The genera placed by Linnæus under this order in his last edition are, *Hystrix* (Porcupines), *Lepus* (Hares, Rabbits, &c.), *Castor* (Beavers, &c.), *Mus* (Rats and Mice, Guinea-Pigs, Agoutis, Marmots, Lemmings, Hamsters, Dormice, Jerboas, the Paca, &c., and the American Flying Squirrel (*Sciurus Americanus volans*, Ray), *Sciurus* (the Squirrels), and *Noctilio* (one of the Bats). [CHEIROPTERA RODENTIA.]

GLOBBA, a genus of Plants belonging to the natural order *Zingeberaceæ*, indigenous in the tropical parts of Asia, especially in the islands of the Indian Ocean and the continent of India, where they extend as far north as 30° along the forest-clad base of the Himalayan Mountains, and even ascend them to elevations of 2000 and 3000 feet; coming into flower in the rainy season. In a family abounding in highly ornamental plants, many of the species of *Globba* are likewise very showy; for the cultivation of which, in European latitudes, a climate and culture are required similar to that so successfully adopted for *Orchidaceæ*. The herbaceous parts yearly die down to the root-stocks; the leaves are distichous, lanceolate, with the sheaths split; inflorescence terminal, loosely panicled or racemose, flowers mostly yellow. In *Globba* is now included the genus *Mantisia*, which was so named from the resemblance of its flower to the Mantis insect; and the species *G. saltatoria*, commonly called Opera-Girls, from the supposed resemblance of the flowers to dancing figures. The fruit of *G uviformis* is said to be eatable.

GLOBE-FISH. [TETRODON.]

GLOBE-FLOWER. [TROLLIUS.]

GLOBIOCEPHALUS. [CETACEA.]

GLOBULARIA'CEÆ, *Selaginaceæ*, *Selagids* of Lindley, a very small natural order of Exogens, nearly allied to *Dipsaceæ*, *Asteraceæ*, *Verbenacea*, and *Myoporaceæ*. The species are herbaceous plants, or small branched herbs. The leaves are alternate, generally sessile, toothed or entire, without stipules, usually in clusters; flowers sessile, spiked with large bracts; calyx spathaceous, or tubular, persistent, with a definite number of teeth or divisions, rarely consisting of two sepals; corolla tubular, hypogynous, more or less irregular, with 5 lobes, imbricated in æstivation; stamens 4, usually didynamous, arising from the top of the tube of the corolla, seldom 2; anthers 1-celled, usually adnate to the dilated top of the filament, rarely versatile; ovary superior; style 1, filiform; stigma nearly capitate; ovules solitary, pendulous, anatropal disc hypogynous, fleshy; fruit 2-celled the cells either separable or inseparable, 1-seeded, membrauous; seed solitary, pendulous; embryo in the axis of a little fleshy albumen; radicle superior. The chief part of this order comes from the Cape of Good Hope. The species are of but little importance. Some are sweet scented. *Globularia Alyssum* is a bitter drastic purgative, once supposed to be the Αλύπον of Dioscorides, and hence called *Frutex terribilis*. *G. vulgaris* has similar properties. Both are emetic.

A twig of *Globularia longifolia*, in flower.

1, the calyx, corolla, and stamens in their natural position; 2, a corolla, separate, with the stamens and style; 3, the ovary enclosed in the calyx, half of which is cut away to expose it. All magnified.

GLOIOCLADIEÆ, a sub-order of Sea-Weeds belonging to the natural order *Cryptonemiaceæ*. The fronds are loosely gelatinous, the filaments of which they are composed lying apart from oue another, surrounded by a copious gelatine. The favellidia are immersed among the filaments of the periphery. It embraces the following genera:—

Cruoria.—Frond crustaceous, skiu-like.

Naccaria.—Frond filiform, solid, cellular; the ramuli only composed of radiating free filaments.

Gloiosiphonia.—Frond tubular, hollow, the walls of the tube composed of radiating filaments.

Nemaleon.—Frond filiform, solid, elastic, filamentous; the axis composed of closely packed filaments, the periphery of moniliform free filaments.

Dudresnaia.—Frond filiform, solid, gelatinous, filamentous, the axis composed of a net-work of anastomosing filaments; the periphery of moniliform free filaments.

Crouania.—Frond filiform, consisting of a pointed filament, whorled at the points, with minute multifid gelatinous ramuli.

(Harvey, *British Sea-Weeds.*)

GLOMERIDÆ, a sub-family of Insects belonging to the family *Chilopoda* and the order *Myriopoda*.

GLORIO'SA, a genus of Plants belonging to the natural order *Liliaceæ*, tribe *Tulipaceæ*, so named from the splendid appearance of its flowers. One species, *G. superba*, is indigenous in most parts of India, with a species, or variety, *G. simplex*, at moderate elevations on the Himalayas, while *G. virescens* is a native of Senegambia. The root is fleshy, the stem climbing, the leaves lanceolate, undulated, and terminating in a tendril serving to support the plaut. The six petals are undulated and reflexed, but pendent before flowering. The nearly horizontal stamens and declinate and oblique style give the flowers a very peculiar appearance, whilo their large size and the red and yellow colour of those of *G. superba* make it worthy of cultivation. This is successfully effected in hothouses. The fleshy root has a bitter and acrid disagreeable taste, and by some is said to be poisonous, but probably without sufficient foundation.

GLOSSOPETRA (γλῶσσα, a tongue, and πέτρα, rock), the name by which mauy early inquirers into the history of organic remains designated a great number of fossil teeth of fishes allied to the shark, which are found abundantly in the upper secondary and tertiary strata of England, France, Germany, Italy, &c. They were also called *Lamiodontes*, *Odontopetræ*, &c.

Amidst the difficulties which embarrassed the naturalists of the 16th century in their attempts to establish the true nature and origin of the organic remains of plants and animals found in the earth [GEOLOGY], the obvious resemblance between the fossil and recent teeth of fishes was a valuable and powerful argument. Fabio Colouna ('De Glossopetris Diss.,' 1627) and Agostino Scilla ('La vana Speculazione,' &c., 1670) pointed out the close agreement, in several cases, between the fossil teeth of Malta, Calabria, &c., and the teeth of living sharks; and the argumeut from similarity of form was made complete by considerations of the peculiar polish, hardness, chemical quality, and even colour of the fossil specimens. Scilla's figures are excellent. Ray, in a letter to Dr. Robinson (1684), makes the same use of the *Glossopetræ*.

"Some other bodies besides shells, commonly esteemed stones, there are found in the earth, resembling the teeth and other bones of fishes, which are so manifestly the very things they are thought only to resemble, that it seems to me great weakness in any man to deny it Such are the *Glossopetræ* dug up in Malta in such quantities that you may buy them by measure and not by tale; and also the vertebres of thorubacks or other cartilaginous fishes there found, and sold for stones, among the *Glossopetræ*, which have no greater dissimilitude to the teeth of a living shark, or the vertebres of a quick thornback, than lying so long in the earth, as they must needs have done, will necessarily induce. Now in this same Isle of Malta we found also many shell-like stones, which why we should not esteem to have been originally the shells of fishes I see no reason; for if in one aud tho same place we find many teeth and hones of fishes entire and unpetrified, aud likewise stones exactly imitatiug the shells of other fishes, a great presumption to me it is that these were originally the things whose shape only they now seem to bear. Neither are these *Glossopetræ* fouud only in Malta, but also iu many places of Germauy, far remote from the sea; in a hill near Aken, in so great plenty, that Goropius makes it an argument they could not be the teeth of sharks. 'In collo illo (saith he) qui Aquis-grano imminet, tantum id genus fuisse piscium quis crederet quantum de Glossopetrarum copiâ conjectari deberet?'"

Llwyd (1698), whose opinions on the real nature and origiu of organic fossils were turned in a wrong channel by the apparent impossibility of understanding how the various animal and vegetable exuviæ could be placed in their subterranean repositories by the Noachiau flood, a proposition which his judgment rejected, describes a considerable number of fish teeth according to the following method:—

Ichthyodontes cuspidati (considered to be incisor teeth of fishes Such of these as are triangular in figure (sagittati), flat with keen and often serrated edges, are called *Glossopetræ*.

Others which are more nearly round, elongated and pointed, he calls *Plectronitæ* (πλῆκτρον, a cock's spur).

Ichthyodontes scutellati (supposed to be molar teeth of fishes). Of these such as were round, umbonate, or scaphoid, were termed *Bufonitæ*.

The angular ones were called *Rhombiscus*.

The flattened pod-shaped teeth were called *Siliquastra*.

In Helwing's curious work, 'Lithographia Angerburgica' (1717), the state of knowledge on the subject in Germany appears little advanced, since he takes the trouble to reject the supposition that the *Glossopetræ* were serpents' tongues. He describes several species of sharks' teeth under the titles of *Glossopetra* and *Odontopetra*.

Until a very recent period there was little progress made in the study of the parts of fossil fishes beyond the views of Llwyd. Neither the *Glossopetræ* nor the *Bufonites* were at all better understood in England, till the successful researches of Mantell in Sussex reawakened the zeal of collectors; and Cuvier, besides renovating the whole subject of recent ichthyology, announced his intention of composing a systematic history of fossil fishes. The drawings which that great man had collected for the purpose were put into the hands of M. Agassiz, whose extraordinary zeal aud success have made a new era in fossil ichthyology. According to the views of this distinguished naturalist, all, or nearly all, the fish teeth known to the early collectors as *Glossopetræ* belong to the family of sharks, which must formerly have been more numerous aud included more various structures than the living races. The *Siliquastra* and other of the scutellate ichthyodontes of Llwyd are likewise teeth of sharks.

The following short synopsis may be convenient to collectors (see also Dr. Buckland's 'Bridgewater Treatise'):—

Family of Sharks.—Group 1, Cestracionts. (*Siliquastra*, *Rhombiscus*, &c. of Llwyd.) Teeth having a broad grinding surface.

2, Hybodonts. (*Plectronitæ* and *Glossopetræ* of Llwyd.) Teeth pointed, striated on both sides.

3, True Sharks. (*Glossopetræ* of Scilla, Llwyd, &c.) Teeth triangular, striated on one side only.

Many of the *Bufonitæ* of old writers belong to the extinct genera *Pycnodus* and *Gyrodus* of Agassiz; though they have often been compared to the teeth of *Anarrhicas lupus*, from which, according to Cuvier, they differ essentially in structure. ('Règne Animal.')

The geological distribution of these fish teeth is curious. Llwyd mentions that scutellate ichthyodontes had not occurred to him in the maritime regions of England, but were found not less plentifully than the cuspidate kinds iu the interior counties, as Oxford, Northampton, Gloucester, Berks, Bucks, &c. This is in agreement with conclusions of later date, for M. Agassiz has found that the whole group of Cestracionts is confiued to strata of the transition and secondary series; while only one of the race (*Cestracion Philippi*, or Port Jackson Shark), is now living.

Dr. Buckland ingeniously remarks, that "the greater strength and flattened condition of the teeth of the families of sharks that prevailed in the formations beneath the chalk had relation, most probably, to their office of crushing the hard coverings of the *Crustacea*, and of the bony enamelled scales of the fishes which formed their food." ('Bridgewater Treatise.')

GLOSSOPHAGA. [CHEIROPTERA.]

GLOSSOPORIS, a genus of Animals belonging to the order *Annelida*, and placed commonly near the Leeches. It has a posterior disc, but it is not suctorial.

GLOSSOPTERIS, a genus of Fossil Ferns, proposed by M. Adolphe Brongniart to include species whose elongated leaves or fronds are covered by fine arched dichotomous often anastomosing nervures. Examples occur in the Carboniferous and Oolitic systems of strata. [COAL-PLANTS.]

GLOTTALITE, a Mineral belonging to the group of *Zeolites*. It occurs crystallised; the crystals appear to be cubic and octohedral. Hardness 3·5. Brittle. Colour white. Lustre vitreous. Translucent. Specific gravity 2·181.

Before the blow-pipe it swells and melts into a white enamel. With carbonate of soda it gives an opaque white bead, and with borax a translucent glass.

It has been found near Port Glasgow, Scotland.

According to Dr. Thomson's analysis it yields :—

Silica	37·014
Alumina	16·308
Lime	23·927
Peroxide of Iron	0·500
Water	21·250
	98·999

GLOTTIS. [LARYNX.]

GLOW-WORM. [LAMPYRIS.]

GLUMACEOUS PLANTS are what are more commonly called *Graminaceæ* and *Cyperaceæ*, to which *Juncaceæ* and a few other orders are occasionally added. They derive their name from the flowers consisting of glumes only.

GLUMALES. [ENDOGENS.]

GLUMIFERÆ, a subdivision of Endogenous Plants, embracing the orders with glumaceous flowers, *Cyperaceæ* and *Graminaceæ*. [CYPERACEÆ; GRAMINACEÆ.]

GLUTTON, the vernacular name for the *Wolverene*. [GULO.]

GLYCE'RIA (from γλυκερός, sweet), a genus of Plants belonging to the natural order *Graminaceæ* and the tribe *Festucineæ*. It has unequal acute sub-membranous glumes, the outer palea with 5-7 strong prominent distinct and parallel ribs, and a scarious margin, subcylindrical, unarmed; the styles terminal. The species are handsome grasses with long stems, and mostly inhabit watery places. The following are the British species of this genus :—

G. aquatica has an erect panicle, repeatedly branched and spreading, rachis semiterete, branches scabrous; spikelets linear, oblong, of 5-10 flowers, outer pale, obtuse; leaves smooth, with slightly compressed sheaths. The root is creeping; stem three to six feet high, smooth, and slightly compressed; sheaths very long; leaves long, rough on the edges and keel; ligule short; panicle large. Branches angular, slender, branched; outer pale, with the central nerve extending to the summit.

G. fluitans has a second panicle, slightly branched, very long; branches nearly simple, roughish; spikelets linear, of 7-12; adpressed lanceolate oblong acute flowers, outer pale, nearly thrice as long as broad; sheaths compressed; stem ascending, rooting below or floating; sheaths nearly smooth, striated; leaves pale green, acute; ligule elongate; panicle remarkably elongated, often nearly simple. Branches without callosities, ascending, lowermost in pairs; spikelets adpressed; outer pale, rather shorter than the inner, with a triangular central point; anthers about five times as long as broad, purple, pale yellow when empty.

G. plicata has a compound panicle; branches compound, nearly smooth, erect when in flower, divaricate with fruit; spikelets linear, of 7-20; oval-oblong rather acute flowers, outer pale, twice as long as broad, sheaths compressed. The sheaths are rough and furrowed. Leaves glaucose, bluntish, plicate when young; ligule shorter; panicle much branched; branches with callosities at the base, lowermost about in fives; outer pale, with three teeth at the end; anther about three times as long as broad, cream-coloured, fuscous when empty. (Babington, *Manual of British Botany*.)

GLYCERINE. [ADIPOSE TISSUE.]

GLYCERIS, a genus of Dorsibranchiate Annelids. It is distinguished by the form of its head, which terminates in a conical fleshy horn-like point, which is divided at the top into four very small tentacles.

GLYCINE. [WISTARIA.]

GLYCYMERIS. [PYLORIDIANS.]

GLYCYRRHI'ZA, a genus of Plants belonging to the natural order *Fabaceæ*, or *Leguminosæ*, consisting of herbaceous plants with pinnated leaves, small flowers in axillary spikes, and roots running very much in the soil in which they grow. The technical character of the genus is given by De Candolle thus :—"Calyx naked, tubular, 5-cleft, bilabiate; the two upper lobes grow together beyond the others. Standard ovate-lanceolate, straight; keel 2-headed or 2 petalled, straight, acute. Stamens diadelphous. Style filiform. Legume ovate or oblong, compressed, 1-celled, 1-4-seeded."

G. glabra, the common Smooth Liquorice, has ovate rather retuse leaflets, somewhat clammy beneath, as well as the branches; stipules wanting; spikes or racemes of flowers pedunculate, shorter than the leaves; flowers distant; legumes glabrous, 3- or 4-seeded. It is a native of the south of Europe from Spain to Tauria, also of China, and is cultivated in France, Italy, Germany, and England for the sake of its roots. The flowers are of a pale blue colour. The name Liquorice, according to Du Theis, is said to be a corruption of the French word 'reglisse,' which is itself a corruption of *Glycyrhiza*. The roots abound in a saccharine mucilaginous matter, which is slightly bitter, and readily soluble in water. A powder, and the well-known common extract, are prepared from it. The decoction in different forms is a common remedy for coughs.

Common Smooth Liquorice (*Glycyrhiza glabra*).

The Common Liquorice-Plant is cultivated in many parts of England, especially about Pontefract, whence the name of Pomfret cakes, applied to a fine preparation of liquorice. Though commonly grown in the field it requires very superior culture in order to produce fine roots for sale in the market. The soil in which it delights to grow is rich black mould, but where this cannot be procured a fresh loam will answer the purpose, provided there is not much wet clay in its composition. It must be at least three feet deep to allow a free passage for the roots, as they are generally expected to be a yard in length, and as the straight ones are more highly prized than those which are crooked. On this account the spade is more useful than the plough in cultivating the ground, and though at first it may be expensive, yet the husbandman will in the end be well repaid for his trouble.

After the ground is fixed upon it must be well covered with good rotten dung, trenched three feet in depth, and left in this state during the winter to be mellowed by frost. About March, if the weather is fine, the plantation should be formed. Plants are either raised from seeds or, as is more commonly the case, from a division of the old roots, which are cut into pieces eight or ten inches long. Choice should be made of those which, as planters term it, have good eyes, that is, buds, and which are more likely to push and grow strong.

A garden line must then be set for the first row, and holes made with the setting stick about a foot and a half apart; into which the sets must be dropped and covered about two inches with soil. The rows must be at least three feet apart, and the plants in one row should be alternate with those of the other; this will not only give them more room, but will have a neat appearance, forming regular rows from whatever part the field is viewed.

"For the first year," says Abercromby, "you may cultivate a light crop of lettuce or onions between the rows. During summer keep the ground free from weeds, and when the subordinate crop comes off hoe and dress the ground. At the close of autumn, or as a winter dressing, fork or dig between the rows to stir and refresh the surface; and cut down the decayed stems. After three or four years' growth the main roots will be of a mature size, and fit for consumption or the market. It is an excellent plan to cover the crowns of the plants in winter with good rotten dung, as it not only preserves them from severe frosts, but is washed down by the rain and becomes valuable nourishment to the roots."

G. echinata has oval lanceolate leaflets, mucronate, glabrous; stipules oblong, lanceolate; spikes of flowers capitate, on very short peduncles; legumes oval, mucronate, 2-seeded, echinated by bristles. It is native of Apulia, on Mount Gardano, and in the northern provinces of China and of Tartary. The whole plant is glutinous to the touch. The roots are horizontal, in taste like the Common Liquorice.

(Don, *Dichlamydeous Plants*; Lindley, *Flora Medica*.)

GLY'PHIS, a genus of Fossil Placoid Fishes from the London Clay. (Agassiz.)

GLYPHISODON, a genus of Acanthopterygious Fishes belonging to the family *Sciænidæ*. The gill-covers are entire, and they have a single row of trenchant and sometimes notched teeth. The species are found in the Atlantic, but are more abundant in the Indian Seas.

GLYPTOCE'PHALUS, a genus of Fossil Cycloid Fishes from the London Clay. (Agassiz.)

GLYPTODON (Owen, so named from the fluted character of its teeth), a genus of extinct Fossil Animals belonging to the order *Edentata*, and allied in form and structure to the modern Armadillos. The first notice of the discovery of the remains of the skeleton of a large edentate animal, with fragments of a tesselated bony armour, similar to that of the Armadillo, appears in the note appended to the end of Cuvier's chapter on the *Megatherium*, in the 4th edition of the 'Ossemens Fossiles,' published in 1823. This notice occurs in an extract from a letter addressed by D. Daniasio Larranaga, curé of Monte Video, to M. Auguste St.-Hilaire. The facts stated in this letter are as follows:—A femur was discovered in the Rio del Lance, branche du Saulis Grande, which weighed 7 lbs.; it was short, but might be from 6 to 8 inches in width; it resembled in every respect the femur of an Armadillo; with it was found a portion of tesselated bony armour, of which the curé promises to send one of the component pieces to M. Auguste Geoffroi. The tail was very short and very stout; it had in like manner a bony armour, but this was not verticillate or disposed in rings. These fossils were stated to have been met with near the surface of the earth, in alluvium or strata of transport, indicative of a very recent epoch. Similar fossils are said to occur in analogous strata near the Lake Nirum, on the frontier of the Portuguese colonies.

These remains were supposed to belong to the *Megatherium*, and Cuvier does not appear to suspect that they belonged to anything else, as he merely remarks that the *Megatherium* had pushed its analogies with the Armadillos so far as to be covered like them with a scaly cuirass.

Subsequently remains of this kind were sent to England, and in the meantime M. Laurillaud and Mr. Pentland, on comparing these with those originally sent to England, came to the conclusion that they belonged to the genus *Dasypus*. This however was doubted by Mr. Clift and Professor Owen, seeing that the conformation of the alveoli of the jaw indicated a dentition differing more widely from that of the existing sub-genera of Armadillos than their respective dental characters differ from one another. "It was at this conjuncture," says Professor Owen, "that Sir Woodbine Parish received the intelligence of the discovery of an entire skeleton, covered with its tesselated coat of mail, about 5 feet below the surface, in the bank of a rivulet near the Rio Matanza, about 20 miles south of the city of Buenos Ayres; and with the account of this remarkable discovery there was at the same time transmitted a drawing or sketch of the whole animal, which has since been lithographed, and one of the teeth of the fossil itself. This tooth Sir Woodbine Parish obligingly submitted to my examination. Its general structure proved it to belong to an animal referrible to the *Edentata* of Cuvier; but its character was so peculiar that I had no hesitation in pronouncing it to differ from that of any known edentate animal, recent or fossil, and from its intimate texture, to be indicative of a new sub-genus of the Armadillo family, for which I proposed the name of *Glyptodon*, in reference to the plated or sculptured character of the tooth."

The *Glyptodon* differs from the *Megatherium* not only in the form and structure but in the number of its teeth, which appear to be eight on each side of each jaw, as in the section of Armadillos called *Cabassous* by Cuvier. It differs from the Armadillos in the form of the lower jaw, and in the presence of a long process descending from the zygoma, in both which respects it resembles, and evidently indicates a transition to the *Megatherium*.

Numerous remains of this curious and interesting animal have been found in various parts of the country, and a very fine specimen, with the coat of mail almost entire, is to be seen in the museum of the College of Surgeons. Portions of this animal are also to be seen in the collection of the British Museum.

Although, when the remains of the *Glyptodon* were first brought to Europe, it was not thought improbable that the *Megatherium* also was inclosed in a gigantic suit of armour, no remains that could be regarded as the tesseræ of such a covering have yet been discovered. It is always difficult however to establish a negative, but the following arguments have been adduced by Professor Owen against this supposition, and will be probably regarded by most naturalists as conclusive:—

"1. The opinion of Cuvier and Weiss, in favour of the *Megatherium* being so armed, rests on no better ground than the mere fact of bony armour of some gigantic quadruped and the skeleton of the *Megatherium* having been discovered on the same continent.

"2. The skeleton, or its parts which have been actually associated with the bony armour above mentioned, belongs to a different and smaller quadruped.

"3. No part of the skeleton of the *Megatherium* presents those modifications which are related to the support of a bony dermal covering.

"4. The proportions of the component tesseræ of the bony armour in question to the skeleton of the *Glyptodon*, are the same as those between the dermal tesseræ and skeleton of existing Armadillos, but are vastly smaller as compared with the bones of the *Megatherium*.

"5. No bony armour composed of tesseræ, having the same relative size to the bones of the skeleton of the *Megatherium*, as in the *Glyptodon* and existing Armadillos, has yet been discovered.

"6. The skeleton of the *Megatherium* has never been found associated with bony armour of any kind, neither have its parts been found associated."

(Owen, *Proceedings of Geological Society*, vol. vii., 2nd series.)

GLYPTO'STEUS, a genus of Fossil Ganoid Fishes, from the Old Red-Sandstone of Elgin and Clashbennie (Agassiz): two British species.

GMELI'NA, an Asiatic genus of Plants named after Gmelin, the author of 'Flora Sibirica,' belonging to the natural order *Verbenaceæ*, of which only one species was formerly known, but five are described by Dr. Roxburgh, and a sixth (with some doubtful species) noticed by Dr. Wallich, in his 'Indian Catalogue.'

The genus is characterised by having a small 4- sometimes 5-toothed calyx, the corolla large, obliquely campanulate, the border irregularly 4-parted, something like those of foxglove in shape, but mostly yellow in colour. Stamens 4, didynamous, with the anthers 2-cleft. Germ superior, 4-celled; cells 1-seeded; attachment sub-superior. Drupe with a nut, from 1- to 4-celled. Embryo erect, without perisperm. All the species of *Gmelina* form shrubs or trees, of which the latter are valued for their timber. They are found in the islands of the Indian Ocean, extending thence into the Malayan and Indian peninsulas. *G. Asiatica* and *G. parvifolia* are common in various parts of India, and *G. arborea* extends from Prome and Martaban even to the Deyra Valley, in 30° N. lat.

The leaves of *G. parvifolia* are remarkable for rendering water very mucilaginous, and are employed medicinally in India; but *G. arborea* (Goombar and Koomhar of the natives) appears to be the most valuable for its timber, as, besides being spread over a wide extent of territory, it attains great size. Dr. Roxburgh mentions it squaring into logs of from 18 to 24 inches, which are occasionally nearly 30 feet long. The wood resembles teak, the colour being the same; the grain rather closer, but it is somewhat lighter. It seems particularly valuable for situations where it is exposed to both the influence of air and of water. One experiment was made by placing part of an outside plank in the river Hoogly, a few miles below Calcutta, "a little above low-water mark, exactly where the worm is thought to exert its greatest powers." Dr. Roxburgh states, that "after remaining three years in this situation, though examined from time to time, the piece was cut, with the view of carrying a specimen of it to England; and to my great joy, I found it as sound and every way as perfect throughout as it was when first put into the river." ('Fl. Ind.,' iii. p. 85.) In another experiment this wood remained good for seven years, while teak, similarly placed, required to be replaced after six years. Hence Dr. Roxburgh suggests experiments on and employment of this wood in ship-building.

GMELINITE, or HYDROLITE, a Mineral belonging to the group of *Zeolites*. It occurs crystallised. Its primary form is a rhomboid; usual form an hexagonal prism; cleavage parallel to the primary planes. Fracture uneven. Hardness 4·5. The colour white, passing into flesh-red; streak white; lustre vitreous; translucent. Specific gravity 2·05.

Before the blow-pipe it increases in bulk, and assumes the appearance of an enamel, but does not melt into a glass. It is found in the Vicentine; at Glenarm, county of Antrim, in cavities in amygdaloidal rocks; and also in North America. [CHABAZITE.]

The following is an analysis by Connell from Glenarm:—

Silica	48·56
Alumina	18·05
Lime	5·13
Soda	3·85
Potash	0·39
Peroxide of Iron	0·11
Water	21·66
	97·75

GNAPHA'LIUM (from γνάφαλον, which signifies the wool which the fuller cuts off in fulling the cloth), a genus of Plants belonging to the natural order *Compositæ*, to the sub-order *Corymbiferæ*, the tribe *Senecionideæ*, the sub-tribe *Gnaphalieæ*, the division *Helichryseæ*. It has the ray-florets pistilliferous, the centre with both stamens and pistils, all of them tubular; the pappus capillary; the receptacle flat, naked; the involucre hemispherical, imbricated; the scales equalling the florets, but not mixed with them. The corolla of the outer florets is often obsolete. The species of this genus have a soft pubescent foliage with dry flowers, which keep for a long time without perishing, and like those of some species of *Helichrysum* and *Xeranthemum*, are called 'everlastings' or 'immortal' flowers. The species are numerous. Five are British. Of these *G. uliginosum* is the most common, growing in wet and sandy places. *G. luteo-album*, *G. sylvaticum*, *G. supinum*, and *G. pusillum* are all rare plants. Several of the species of the old genus *Gnaphalium* are referred to new genera as *Antennaria* and *Filago*. *G. dioicum* is *Antennaria dioica* of Gærtner. It grows on mountain heaths in Great Britain, and is commonly called Cotton-Weed, and by the older herbalists Pes Cati. Its flowers were admitted into the older pharmacopœias under the name of 'Flores hispiduli Pes Cati.' They are astringent, and were employed in the cure of hooping-cough, phthisis, and hæmoptysis. *G. arenarium* (*Helichrysum arenarium*) has been employed as a remedy in dyspnœa. *G. Stœchas* of Linnæus, Goldilocks, the *Helichrysum Stœchas*, is mentioned by Theophrastus ('Hist. Pl.' 9, 21). The flowers of this plant were formerly much used in medicine, but are seldom employed at the present day.

(Babington, *Manual of British Botany;* Burnett, *Outlines of Botany;* Fraas, *Synopsis Plant. Fl. Classicæ.*)

GNAT. [CULICIDES.]

GNA'THODON, a genus of Conchiferous *Mollusca* with the ligament inclosed in the cartilage pit, established by Dr. Gray. This peculiarity of structure is also found in a new genus *Mulinia*.

GNATHO'STOMA (γνάθος, a jaw, and στόμα, the mouth), a genus of Nematoid *Entozoa* [ENTOZOA], discovered by Professor Owen in the stomach of the tiger. These worms, the largest of which are about an inch in length and a line in diameter, were found in the substance of several small cellular tumours situated immediately beneath the mucous membrane of the stomach, and apparently formed by the condensation and thickening of the submucous cellular tissue, which was probably owing to the irritation of the *Entozoa*. Only a pair of these animals was found in each tumour, and they always consisted of male and female, the former of which was about one-fourth smaller than the latter.

In both sexes the body is round, elastic, and attenuated at both extremities; the tail is more obtuse and bent in the male; the head is obtuse and truncated in both of them. The integuments are transparent, and, from the intestinal and genital tubes showing through the surface of the body, appear to be striated transversely. The anterior two-thirds of the body are covered with a circular series of minute reflected spines, each furnished with three points. The mouth is surrounded by a tumid circular lip, and armed with several rows of spinous processes of a similar structure to those on the body. The orifice of the mouth itself is bounded on each side by a jaw-like process (whence the name of the genus), the anterior margin of which is formed into three straight horny points, or processes, directed forwards. The male organ of generation consists of a slightly-curved slender spiculum, not furnished with a sheath as in the *Strongylus*, and surrounded by eight distinct pointed papillæ.

The most interesting point in the internal structure of this entozoon, and which does not appear to have been hitherto detected in any other animal of this class, is the existence of a distinct salivary apparatus, similar to what is found in the *Holothuria* and other *Echinodermata*. "This apparatus," says Professor Owen, "consists of four elongated straight blind tubes, each about two lines in length, which are placed at equal distances around the commencement of the alimentary canal, having their smaller extremities directed forwards, and opening into the mouth, and their closed obtuse ends passing backwards into the abdominal cavity. When examined with a lens of a quarter of an inch focus, the parietes of these salivary tubes present very distinct oblique or spiral decussating fibres; their contents are semi-pellucid in the recent worm, but become opaque in spirit of wine." The existence of this salivary apparatus along with the more perfect organs of mastication, as the jaws, in this entozoon is highly interesting, as it shows an approximation to the structure of the digestive organs in the higher classes of animals.

Professor Owen has since found the *Gnathostoma* in the stomach of other animals of the Cat kind, as the leopard.

Beautiful preparations of both the male and female worms dissected are preserved in the museum of the College of Surgeons in London.

GNEISS, a German term for the lowest series of stratified primary rocks, the introduction of which marks the obligations which British geologists owe to the school of Werner; while such terms as lias, cornbrash, gault, &c., record the original discoveries of Smith and other English writers. As there are no organic remains in the gneiss strata, and the variations of its composition and structure appear independent of the relative antiquity of the deposits, it is impossible, except by the help of the included limestones, quartz-rocks, clay-slates, &c., even to attempt the division into formations of the vast thickness of the gneiss strata which appears in the Highlands of Scotland, the mountains of Scandinavia, &c.

Gneiss is generally a compound of the same three minerals as granite, namely, quartz, felspar, and mica. In the same manner as granite varies in the proportion of its ingredients, the magnitude of the component crystals, the absence of mica, or the substitution of other minerals for it, so gneiss exhibits corresponding variations.

Dr. M'Culloch, whose examination of the gneiss tracts of Scotland was very complete, presents an extended synopsis of the varieties of gneiss which he had observed. His table includes indeed a great number of mineral compounds different from the general character of gneiss, but is nevertheless valuable to the geologist. He considers gneiss in three divisions: first, of regular composition, containing at least three of the four minerals—quartz, felspar, mica, and hornblende; secondly, of irregular composition, containing compact felspar; and thirdly, of irregular composition in other respects. ('Treatise on Rocks.')

The following is a synopsis of the first division:—

Granitic Gneiss.—This is always large grained.
- *a.* Composed of quartz, felspar, and mica.
- *b.* Composed of quartz, felspar, and hornblende.
- *c.* Composed of quartz, felspar, mica, and hornblende.

Schistose Gneiss.—The structure is foliated like mica-schist, or granular like quartz-rock.
- *a.* Composed of white felspar and quartz in minute grains with rare scales of mica (resembles quartz-rock).
- *b.* Composed of felspar and quartz as above, but with abundance of mica (so as to resemble mica-schist).
- *c.* In this the mica is extremely abundant, so as to form continuous laminæ.
- *d.* In this the mica is predominant, and there are large interspersed crystals of felspar.
- *e.* Composed of large grains of quartz and felspar with little mica.

Laminar Gneiss.—Each substance occupying a distinct lamina.
- *a.* Composed of quartz and felspar.
- *b.* Composed of quartz, felspar, and mica.
- *c.* Composed of quartz, felspar, and hornblende.
- *d.* Composed of felspar and hornblende.
- *e.* Composed of quartz, mica, and hornblende.

All the varieties of rock comprised under the title of gneiss are stratified, the beds varying much in thickness, and being most remarkably subject to contortions both on a large and small scale, especially where granite veins cross the laminæ.

Gneiss is an interesting rock for study to the English geologist. Over a considerable portion of the mainland, and in the western islands of Scotland, gneiss is the predominant and fundamental rock. It is also found abundantly in Ireland. The picturesque features of gneiss present almost every imaginable variety, a broad expanse occupied by this rock sometimes extending over considerable tracts, and being only relieved in its savage monotony by occasional pools of water or patches of bog; while in other districts it forms wild and rugged hills, assuming a mountainous character, and displaying broken and craggy faces of rock. (Ansted.)

Gneiss admits of considerable variety by the substitution of other minerals for either the quartz, felspar, or mica of which it is usually composed. The mica, for instance, may be replaced by talc, forming what is called Stratified Protogine. In some cases hornblende is superadded to the ordinary materials, forming a syenitic gneiss.

GNETA'CEÆ, *Joint-Firs*, a natural order of Plants belonging to the small class of Gymnosperms. The species consist of small trees very much branched, or of sarmentose shrubs with opposite or clustered branches, and thickened separable articulations. The leaves are opposite, entire, with pinnate veins, sometimes very minute and scale-shaped. The ligneous tissue of the wood is marked with circular discs. The flowers are monœcious or diœcious; the stamens are contained in a 1-leaved calyx; the ovary is perforated at the apex, containing in a single cavity a solitary erect ovule; the ovule pointed by a stylo-like process, formed from the membrane of the nucleus; there is no trace of a style or stigma.

This small order of plants has been formed by Blume, whose memoir in the 'Annales des Sciences Naturelles' contains the principal knowledge we have of this order. "This little family," he says, "constitutes a part of that natural class of vegetables in which the fertilisation of the ovule takes place immediately, without the aid of style or stigma, through the foramen of the ovule itself. Through *Ephedra*, which has hitherto been placed with *Coniferæ*, the order is closely connected with the latter: and, on the other hand, it tends towards *Casuarinaceæ*, plants of a higher degree of organisation; since *Gnetaceæ* is beyond all doubt an instance of a more perfect kind of evolution than either *Coniferæ* or *Cycadaceæ*. From both these orders *Gnetaceæ* differ in the greater perfection of their sexual organs, especially of their stamens; and at the same time their ovules are not absolutely naked, but covered with a pericarpial integument pierced at the summit. In the male flowers the perianth is tubular; at first quite closed up, in the manner of certain *Artocarpeæ*, but eventually it is ruptured by the rising of the stamen. There is no trace of a perianth of this sort in the neighbouring orders; but in *Coniferæ* a totally different organisation of anther occurs, that part not opening, as in *Gnetaceæ*, by transverse pores of the apex, but always at the side, and generally longitudinally."

The species of this family are natives of the temperate parts of Europe, Asia, and South America. *Gnetum* is an inhabitant of the hottest parts of India and Guyana.

Some of the species of *Gnetum* are used as food. The seeds of *G. Gnetum* are eaten in Amboyna, and are roasted, boiled, or fried. The green leaves are cooked and eaten like spinach. The inside of the fruit of *G. urens* is lined with stinging hairs; the seeds are, however, eaten; the stem exudes a transparent gum, and when cut across yields a large quantity of transparent water, which is drunk.

GOAT. [CAPREÆ.]

GOAT'S-BEARD. [TRAGOPOGON.]

GOAT-MOTH. [COSSUS.]

GOAT-PEPPER. [CAPSICUM.]

GOAT-SUCKERS, the English name of those Night-Swallows commonly termed Night-Jars; whence the name *Caprimulgidæ*, by which the family is generally known among ornithologists. Mr. Rennie changes the name of the European Night-Jar to *Nyctichelidon* (Night-Swallow), objecting that the name Goat-Sucker, which it has received in all languages, and which, he thinks, has been most absurdly continued by systematic naturalists in the term *Caprimulgus*, shows the opinion of it entertained by the vulgar. Now we cannot admit this great absurdity, though we entirely agree with Mr. Rennie that "it is as impossible for the night-jar to suck the teats of cattle (though most birds are fond of milk), as it is for cats to suck the breath from sleeping infants, of which they are popularly accused." If every zoological name that has not a sure foundation were to be changed, there would be no small alteration in nomenclature and not a little confusion; as it is, the perpetual change of names is quite sufficiently perplexing. Nor are we at all sure that such names as *Caprimulgus* are not of some value as showing, in connection with a true history of the habits of the bird, how the errors and superstitions of old times have vanished before the light of modern investigation. Thus much as an apology for not changing the family name *Caprimulgidæ*.

Mr. Vigors remarks that when we search among the Perchers for that point where they approximate the Owls, we at once light upon a group, the *Caprimulgus* of Linnæus, whose general appearance and habits point out the affinity. "The nocturnal and predatory manners of this genus," says Mr. Vigors, "the hawking flight, the legs feathered to the talons, the large ears and eyes, the very disc that surrounds the face, and the pectination of the external quill-feathers, observable in some of the species, the general softness of the plumage, together with its peculiarly striking colour and markings, produce a similarity between it and the *Strix* that has attracted the eye of the common observer no less than the naturalist. The provincial names of this genus have generally a reference to this resemblance; while the earlier scientific describers of the different species have for the most part ranked them with the owls. I know not whether the singular character observable in some of the species of this family, the serrated nail of the middle toe, may not be cited as an additional proof of their approach to the birds of prey. The strong toes of the latter are lost in *Caprimulgus*: but a construction of similar import (for the serration of the nail appears capable of being applied to the purposes of seizure only), preserves, though faintly, the resemblance. May we not almost venture to affirm that this apparently trivial appendage is an instance of that beautiful shading by which nature softens down the extremes of her neighbouring groups —one of those minute and delicate touches by which she marks at once an affinity and a deviation? But while we may discern at a glance the general approximation of these two families, we must at the same time acknowledge that they stand in need of an intermediate link to give them a closer connection. The weakness of the bill and of the legs and feet of the *Caprimulgus* still keeps it at some distance from the owls, in which the same members are comparatively strong; while the wide gape of its mouth serves to divide the families still further. A connecting link has been however supplied by an Australian group, the *Podargus* of M. Cuvier, which harmonises these discrepant characters. We have an opportunity of observing among the specimens in the collection of the Linnean Society, how far the bill of this extraordinary genus combines the different forms of that of the two genera, and how far the legs, still maintaining the characteristics of *Caprimulgus*, such as the unequal length of the toes, are related to those of *Strix* by their superior robustness. Here indeed there is a beautiful gradation of affinities. All the front toes of *Caprimulgus* are united by a connecting membrane as far as to the first joint; those of *Strix* are divided to the origin; while those of *Podargus* partake of the characters of both, in having the middle toe connected with the outer, but divided from the inner. Again, as I have already remarked, *Caprimulgus* has the nail of the middle toe dilated and serrated: *Strix* has it, generally speaking, undulated and entire at the margin; but in *Podargus* the same part displays the singular dilatation of the one and the marginal integrity of the other It is difficult to say to which of these groups it comes nearest, until further and more accurate accounts than we at present possess of its food and economy may determine its actual situation. At present it remains oscillant between the two families, and may decidedly be pronounced the immediate passage from the birds of prey to the perchers." Mr. Vigors adds in a note that he had latterly obtained accounts from actual observers of some of these *Podargi* in Australia stating their manners to be generally conformable to those of th *Caprimulgi*.

Mr. Vigors further observes that the union between the two families of *Caprimulgidæ* and *Hirundinidæ* in the most essential particulars, in the habits, economy, and general conformation, is too evident to the common observer, and too universally acknowledged by scientific writers, to need any further illustration. But he remarks that it is gratifying to observe how, even in minute particulars, a gradual succession of affinities imperceptibly smooths the passage between conterminous groups; nor does he pass over without remark the circumstance of the hind toe of *Caprimulgus* being usually retractile, which enables it to place all its toes in front, in a similar position to that which they maintain in *Cypselus*, where the family of the *Hirundinidæ* terminates. He notices also the conformation of the tail in the two families as showing a similar affinity, observing that some species of *Caprimulgus*, then lately arrived from Brazil, exhibit the forked tail of *Hirundo*, one of which, indeed, the *C. psalurus* of Temminck, has this character developed to an almost disproportionate degree. "Leaving those typical families," continues Mr. Vigors, "with the short bill, and taking a general survey of the tribe, we may perceive that the *Caprimulgidæ* unite themselves to the longer-billed families, by means of the Linnean *Todi*, which preserve the broad base of the bill of the latter, but lead on, by comparative length of that member, to the succeeding family of *Halcyonidæ*. If we compare the bill of the type of the last-mentioned genus, the *Todus viridis*, Linn. [MUSCICAPIDÆ], with those of *Caprimulgus* and *Halcyon* [KINGFISHERS], we shall perceive that it stands exactly midway between them in the relative proportions of strength and breadth which it bears to each. In the length also of the tail, an important character in the groups that feed on the wing, it maintains a middle station between them." For the group which forms the immediate connection between the present family of *Todidæ* and the preceding *Caprimulgidæ*, Mr. Vigors observes that we are indebted to Dr. Horsfield, since in the depressed and broad-based bill and wide gape of *Eurylaimus* we recognise the characters which unite those families [MUSCICAPIDÆ], and Mr. Vigors refers to the valuable plates of the 'Zoological Researches in Java' as exhibiting the intimate approach of the bill of this latter genus to that of *Podargus Javanensis*. Near to *Eurylaimus*, which in the opinion of Mr. Vigors is united to *Todus* by some species now referred to the former genus, but which were originally included in the latter, he would place the genus *Eurystomus* of Vieillot [MEROPIDÆ], which in the essential characters of the bill, and from all Mr. Vigors could ascertain of its general habits and economy, seems to him to bear a striking affinity to the present group. Here also the same considerations would incline him to arrange the *Calyptomena* of Sir Stamford Raffles, which differs chiefly from the groups now mentioned in its comparatively shorter bill and the singular covering of plumes that project over the upper mandible. All these and some other corresponding genera will be found, Mr. Vigors makes no doubt, on more accurate knowledge of their economy, to belong either to the present family, which is placed at the extremity of the *Fissirostres*, or to that of *Pipridæ*, which forms, in the system of Mr. Vigors, one of the aberrant groups also of the neighbouring circle of *Dentirostres*, and thus comes in contact with the *Todidæ*. Mr. Vigors admits that more extensive knowledge respecting these birds will determine the line of demarcation between them; but the general affinity by which they approach each other, at least, in continuous families, may at once, in his opinion, be decided without hesitation. ('On the Natural Affinities that connect the Orders and Families of Birds,' 'Linn. Trans.,' vol. xv.)

Mr. Swainson ('Classification of Birds') considers the order of *Fissirostres* to be best represented by the Swallows and Goat-Suckers; observing at the same time that the former are the most isolated, whilst the latter, above all other birds, show the nearest affinity to the Owls. "No species indeed," says Mr. Swainson, "has been yet discovered which would perplex a naturalist to decide to which of these families it belonged, but that is not material; we do not uphold the injudicious theory that every one of nature's links is so perfect, or rather so well known, as to leave no unequal intervals in the series; on the contrary, we maintain that such interruptions are frequently found, and in this manner are the Goat-Suckers detached by a slight interval from the Owls." The same author remarks that the Fissirostral Birds, as a whole, are peculiarly distinguished by having the powers of flight developed in the highest degree; all the energies of their nature, he observes, seem concentrated in this one perfection; for their feet are always very short, weak, and generally so imperfect as to be of use only to rest the body after flight; their food being exclusively insects captured upon the wing. "To accomplish this," proceeds Mr. Swainson "nature has given to their mouth an enormous width, by which, superadded to their amazing flight and rapidity of movement, they are almost sure to capture their prey. Who that has watched the swallow or the goat-sucker has failed to recognise these peculiar perfections? As the nocturnal goat-suckers frequently prey upon beetles and large moths, the mouth, in such species, is defended by stiff bristles; but these appendages are rendered unnecessary to the swallows; their game consisting entirely of those little soft insects seen in the air on a summer's evening or sporting on the flowers of a sunny field. The goat-suckers choose the twilight, and catch their food precisely in the same way, excepting, indeed, that their little short feet are sometimes used for the same purpose, a most singular part of their economy, first noticed by our countryman White. Some of these nocturnal birds (*Poyardus*,* Cuv.) have a bill nearly as strong as an owl's; others are furnished with forked tails of excessive length; and one species, discovered during our researches in Brazil (*Caprimulgus diurnus*, Temm.) quits the nocturnal habits of its congeners, and in cloudy days may be seen in troops of 15 or 20 skimming over the surface of ponds, precisely in the manner of swallows." Mr. Swainson then remarks that the Swallows and the Goat-Suckers are, in fact, connected by certain swifts, for the Balassian Swift is described as a nocturnal bird, appearing at sunset and going to rest at sunrise; and thus he enters the family *Hirundinidæ*. [HIRUNDINIDÆ.]

The *Caprimulgidæ*, according to Mr. Swainson's classification, consist of the following genera and sub-genera. But it should be remembered that he states that he has thought it best not to attempt a natural arrangement until the family is better understood.

The following are the characters of the family:—Plumage lax, soft. Bill exceedingly small; gape enormous; feet very short, weak; the hallux directed forwards. (Swainson.)

Podargus, Cuvier.—Size large; the middle claw not serrated; the hallux not directed forward.

Sub-genera, *Podargus* proper.—Bill large, very strong, the tip and margins of the upper mandible folding over those of the lower; culmen elevated and arched; true rictal bristles none; tongue very thin, entire; tarsus short. (Swainson.)

Several species of this sub-genus have been found in Australia, and we select as an example of these—

P. humeralis.—It is variegated above with ashy brown and dirty yellow; head and sides of the back conspicuously striped with black; forehead and dorsal plumage lightly dotted and banded with white; tesselated beneath with black stripes and approximating dirty yellow bands. Length of the body 20 inches, and of the tail 8½ inches.

Cold-River Goat-Sucker (*Podargus humeralis*).

Mr. Vigors and Dr. Horsfield observe that the birds of this genus in the collection of the Linnæan Society bear such a general resemblance to each other, that they felt some hesitation in describing them as different species. The careful examination of many individuals in their own country will, in the opinion of these zoologists, alone determine with certainty whether they are distinct or merely varieties of the same species from age or sex. They state however that Dr. Latham, as well as themselves, distinguished this as a species under the name of the Cold-River Goat-Sucker from the Wedge-Tailed Goat-Sucker (*Podargus Stanleyanus*). Mr. Swainson also cites it as a species.

* *Podargus* must be meant.

P. Javanensis of Horsfield, the Chabba-Wonno of the Javanese, is an Asiatic example of this genus. In general colour it is ferruginous or rufous, with a tint of isabella, varied by undulated transverse bands of dark brown; a collar of pale whitish isabella, variegated with two very narrow bands of deep brown, passes round the lower part of the neck, and from this collar several large irregular white marks are disposed in an interrupted series from the axilla to the middle of the back; on the breast and belly several white feathers are scattered; the transverse bands are strongest on the rounded tail; feet rufous; claws blackish; bill obscure yellow and rather shining; middle toe not dentated. Length, 9 inches.

Chabba-Wonno (*Podargus Javanensis*).

The habits of this bird are not known. It is nocturnal, and conceals itself in large forests.

The other two sub-genera arranged by Mr. Swainson under the genus *Podargus* are *Ægotheles*, Horsfield and Vigors, and *Nyctibius*, Vieillot.

Mr. Allis has stated that the sclerotic ring of the great *Podargus* does not present the slightest appearance of distinct plates, being simply a bony ring.

M. Lesson is of opinion that *Steatornis* [GUACHARO BIRD] forms the passage between the *Caprimulgi* and the Crows.

Caprimulgus, Linnæus.—Bill remarkably small and weak; the sides inflexed and sometimes gaping; tarsus short; all the toes directed forwards; the inner and outer toes equal; the middle claw pectinated. (Swainson.)

Mr. Swainson subdivides the genus into the following subgenera:—

Caprimulgus.—Gape strongly bristled; tail lengthened, rounded; lateral toes equal. (Swainson.)

C. Europæus, the Common Goat-Sucker. The male has its plumage above and that of the throat ash-gray, thickly streaked and spotted with brown mostly of a yellowish tinge; head and neck with longitudinal blackish streaks; a white stripe beneath the base of the lower mandible extends along each side of the lower part of the head, and there is a central patch of white upon the throat; quills with the outer webs blotched with reddish-brown, and the three exterior feathers with a large white patch near the tips of the inner webs; tail irregularly marked and indistinctly barred with blackish-grey and yellowish-brown; the two external feathers on each side white at their termination; plumage of the under parts yellowish-brown, with transverse blackish bars; bill and irides dark brown; tarsi paler. Female with the plumage of the male generally, but she wants the white spots on the quills and tail-feathers.

This is most probably the Αἰγοθήλας (or Goat-Sucker) of Aristotle and the Greeks, and the *Caprimulgus* of Pliny and the Romans. There is indeed, as we shall presently see, another European species, but it is very rare. The *Caprimulgus Europæus* is the Calcabotto Piattaglione, Porta Quaglie, Boccaccio, and Cova-Terra, of the Italians; Chotacabras of the Spaniards; Tette-Chevre, Engoulevent Ordinaire, and Crapaud Volant, of the French; Milchsauger, Geissmilcher, Nacht Rabe, Nacht Schwalbe, and Tag-Schlafer, of the Germans; Natskraffa, Natskarra, and Quallknarren, of the 'Fauna Suecica;' Nat-Ravn, Nat-Skade, and Aften-Bakke, of Brunnich; Muckenstecker and Nachtrabb of Kramer; Aderyn y droell, Rhodwr of the Welsh; and Goat-Sucker, Night-Jar, Jar-Owl, Churn-Owl, Fern-Owl, Dor-Hawk, Night-Hawk, and Wheel-Bird, of the English.

Common Goat-Sucker (*Caprimulgus Europæus*).

The absurd story of the goat-sucking habits of this bird may be traced back as far as the time of Aristotle, and is probably of much older date. It has all the appearance of a deep-rooted popular prejudice, which was so extensively believed when that zoologist wrote, as to demand, in his opinion, insertion in his 'History of Animals.' In the ninth book of that history (c. xxx.), Aristotle says, "The bird called *Ægothēlas* is a mountain-bird, a little larger than the blackbird (κοττύφου), and a little less than the cuckoo. It lays eggs to the number of two or three at most, and is of a slothful nature (βλακικός). Flying upon the goats, it sucks them (θηλάζει δὲ τὰς αἶγας προσπετόμενος), whence it has its name. They say that when it has sucked the teat it becomes dry, and that the goat becomes blind. It is not sharp-sighted by day; but it sees by night." Ælian's version of the effect of the bird's sucking is confined to the part sucked. He says that the operation makes the teat dry or blind (τυφλοῖ μασθόν), and so the flow of the milk is stopped. He speaks of the great audacity of the bird, observing that it is fearless of the vengeance

Head and foot of Common Goat-Sucker (*Caprimulgus Europæus*).

of the goatherds (iii. 39). Ælian also refers to its goat-sucking propensity in c. 22 of book xvi. Pliny ('Nat. Hist.,' ix. 40) states that the "*Caprimulgi* are nocturnal thieves: for they cannot see by day (interdiu enim visu carent). They enter the folds (stabula), and fly to the udders of the goats in order to suck the milk, from which injury the udder dies away, and blindness falls upon the goats which have been so sucked." Nor is the charge of goat-sucking the only false accusation made against the Night-Jar. White ('Selborne') informs us that the country-people have a notion that the fern-owl, or churn-owl, or eve-jarr, which they also call a puckeridge, is very injurious to weanling calves, by inflicting, as it strikes at them, the fatal distemper known to cow-leeches by the name of puckeridge. "Thus," says White, "does this harmless ill-fated bird fall under a double imputation, which it by no means deserves; in Italy, of sucking the teats of goats, whence it is called the *Caprimulgus*, and with us, of communicating a deadly disorder to the cattle. But the truth of the matter is, the malady is occasioned by the *Œstrus bovis*, a dipterous insect, which lays its eggs along the chines of kine, where the maggots, when hatched, eat their way through the hide of the beast into the flesh, and grow to a very large size." (White, 'Selborne.') Belon, in his folio edition (1555), gives no figure of this species, but appears to confound it with an Owl, 'L'Effraye' or 'Fresaye.' In the small 4to. 'Portraits d'Oyseaux,' &c. (1557), a figure is given at the end of the owls, which, though bad, cannot be mistaken for anything but the Goat-Sucker, with the titles of 'Αἰγοθήλας, *Strix Caprimulgus, Fur nocturnus*, Effraye, Frezaye,' with the following old quatrain:—

"Le hideux cry de la Frezaye effraye
Celuy qui l'oit: elle vole de nuict,
Et à tetter les chevres prend deduict.
T'esbahis-tu s'elle se nom Effraye?"

The food of the European Goat-Sucker consists chiefly of night-flying and evening-flying moths and beetles, *Phalænæ, Melolonthæ*, &c. In the stomach of one which Willughby opened were seeds as well as beetles. The Fern-Chafer, *Melolontha solstitialis*, seems to be a favourite food, and hence the bird is frequently found in those neighbourhoods where fern abounds. It spends the summer in the temperate countries of Europe, but on the approach of winter retires to the south of the Mediterranean Sea. Its arrival in these islands may be looked for from the middle of May to the end of that month, and its departure takes place towards the end of September or beginning of October. The earliest appearance of the bird in White's 'Calendar' is dated on the 1st of May, and the latest on the 26th of that month. The last-named naturalist paid particular attention to the habits of this species. "There is no bird, I believe," writes that delightful observer, in a letter to Pennant, "whose manners I have studied more than that of the *Caprimulgus* (the Goat-Sucker), as it is a wonderful and curious creature; but I have always found that though sometimes it may chatter as it flies, as I know it does, yet in general it utters its jarring note sitting on a bough; and I have for many an half-hour watched it as it sat with its under mandible quivering, and particularly this summer. It perches usually on a bare twig, with its head lower than its tail, in an attitude well expressed by your draughtsman in the folio 'British Zoology.' This bird is most punctual in beginning its song exactly at the close of day; so exactly that I have known it strike up more than once or twice just at the report of the Portsmouth evening gun, which we can hear when the weather is still. It appears to me past all doubt that its notes are formed by organic impulse, by the powers of the parts of its windpipe, formed for sound, just as cats pur. You will credit me, I hope, when I assure you that, as my neighbours were assembled in an hermitage on the side of a steep hill, where we drink tea, one of these churn-owls came and settled on the cross of that little straw edifice and began to chatter, and continued his note for many minutes; and we were all struck with wonder to find that the organs of that little animal when put in motion gave a sensible vibration to the whole building! This bird also sometimes makes a small squeak, repeated four or five times; and I have observed that to happen when the cock has been pursuing the hen in a toying way through the boughs of a tree." Again:—"On the 12th of July I had a fair opportunity of contemplating the motions of the *Caprimulgus*, or Fern-Owl, as it was playing round a large oak that swarmed with *Scarabæi solstitiales*, or Fern-Chafers. The powers of its wing were wonderful, exceeding, if possible, the various evolutions and quick turns of the swallow genus. But the circumstance that pleased me most was, that I saw it distinctly, more than once, put out its short leg, while on the wing, and by a bend of the head deliver somewhat into its mouth. If it takes any part of its prey with its foot, as I have now great reason to suppose it does these chafers, I no longer wonder at the use of its middle toe, which is curiously furnished with a serrated claw." Mr. Vigors (loc. cit.) remarks that the Common Barn-Owl (*Strix flammea*) possesses the same character of serrated unguis: and that some other species of the *Strigidæ* exhibit somewhat of the rudiments of it; thus establishing more closely the affinity of the Owls and the *Caprimulgi*. Mr. Vigors adds that his conjecture as to the use of the serrated claw—that is, its being devoted to the purposes of seizure—is considerably corroborated by the passage from White above quoted. At the same time he refers to Wilson, who in his account of the *Caprimulgus Carolinensis* (*Antrostomus Carolinensis* of Prince C. L. Bonaparte) assigns a different use to this serrated claw. Of this species Wilson says, "Reposing much during the heat of the day, they are much infested with vermin, particularly about the head, and are provided with a comb on the inner edge of the middle claw, with which they are often employed in ridding themselves of these pests, at least when in a state of captivity." Upon this Mr. Vigors observes that such can be at best but an accidental use to which the serration can be applied. There are many other groups of birds, he adds, possessing the same character, to which the same application of it can never be assigned—for instance, the greater part of the genus *Pelecanus* of Linnæus. Many of these birds, whose feet, Mr Vigors observes, are naturally ill adapted by their webbed structure for laying hold of any object, are yet found to incubate among trees, where the serrated claw may give them a further power of prehension; they are also, he remarks, asserted to seize their prey occasionally with the foot; in which acts the structure of the nail, as in the case cited by White respecting the *Caprimulgus*, may be peculiarly useful. "The family of the *Ardeidæ* among the wading birds equally exhibit," says Mr. Vigors, in conclusion, "an analogous construction in the middle nail. Here again this character seems adapted to their mode of life in enabling them to hold their prey more firmly in those slimy and muddy situations where it might otherwise elude them; while, at the same time, it may assist their feet (which, like those of the *Pelecanidæ*, are naturally ill suited for grasping) in their hold among the trees, where, like some also of the latter family, they build their nests." Mr. Dillon is of opinion that the chief use of the serrated claw is simply to comb out or dress the vibrissæ which surround the gape. Mr. Swainson opposes this view, observing that there is an American group of this family which have no bristles round the bill, and yet have the serrated claws; and another group in Australia which have bristles round the bill, and yet with the claw smooth and simple. He also observes that the Heron tribe have the gape smooth, but the claw serrated. Mr. Rennie remarks that the passage in Wilson "appears to settle the question;" but he gives no satisfactory reason why.

Psalurus macropterus (old male).

The Goat-Sucker is sometimes to be seen abroad in gloomy days; we have seen it on such days, and generally on the ground. On a tree it is observed to perch not across a branch, but on its longitudinal direction. These birds affect the neighbourhood of oaks, where in May they find the *Melolontha vulgaris*, and at Midsummer the *M. solstitialis*. White graphically describes the evolutions of one round his 'great spreading oak,' where it was hawking after a brood of some particular *Phalæna* belonging to that tree. On this occasion he says it exhibited a command of wing superior to the swallow itself. The same author states that when a person approaches the haunts of this species in an evening they continue flying round the head of the obtruder; and by striking their wings together above their backs, in the manner that the pigeons called Smiters are known to do, make a a short snap; perhaps at that time, he adds, they are jealous of their young, and their noise and gestures are intended by way of menace. The eggs, two in number, oblong, white or dusky, and streaked somewhat like the plumage of the bird, are equal in size at each end, and are laid on the bare ground, generally among fern, heath, or long grass, sometimes in furze-brakes or woods, but always near the latter. Montagu describes the noise made by the male during incubation when perched, and with his head downwards, as not unlike that of a spinning-wheel, and notices its uttering a sharp squeak as it flies.

The other European species, *Caprimulgus ruficollis*, which is very rare, has been shot in the oak-woods some miles distant from Algeziras, and also in the valley of the Rio del Mel, near that city. The Spanish name for it is Samala. Mr. Gould has no doubt that its natural habitat is Northern Africa. Prince Bonaparte notes it as occurring in south-western Europe during the summer.

Mr. Gould has established a new genus for some of the American *Caprimulgi*, under the name of *Antrostomus*. [WHIP-POOR-WILL.]

Psalurus (Sw.).—Gape strongly bristled. Tail excessively long, and very deeply forked.

P. macropterus. A bright ruddy demi-collar ornaments the back part of the neck, and the two external tail-feathers in the male are much longer than the others. The tail of the female is much shorter. It is a native of Paraguay and Brazil.

Chordeiles (Sw.).—Gape perfectly smooth. Wings very long, equal to the tail, which is slightly forked.

C. Americanus. Ground of plumage above, sides of the head, and front of the neck, dark liver-brown, glossed with greenish. Head, neck, and upper rows of lesser wing-coverts, spotted with yellowish-brown; back, scapulars, and tertiaries, mottled with brownish-white and a little wood-brown, the pale colour forming speckled bars on the tail and its coverts; intermediate wing-coverts more thickly mottled with a purer white: greater coverts spotted with brown on the margin; band on middle of quills, beginning on the inner web of the first and ending with the fifth, and a broad arrow-shaped mark on the throat, pure white. A white dotted superciliary band reaches to the nape. Lateral tail-feathers banded with white. Plumage below and inner wing-coverts barred alternately with brownish-white and liver-brown. Bill blackish. Legs pale. Tail forked. Middle toe, which is longest, with a serrated claw.

This is the *Caprimulgus Americanus* of Wilson, and the *C. Virginianus* of Prince Bonaparte, who notices the bird in his 'Geographical and Comparative List,' as *Chordeiles Virginianus* (Bonap.), and *Caprimulgus Popetue* (Vieill.). It is the Peesquaw of the Cree Indians.

Sir John Richardson says that few birds are better known in the Fur Countries than this, which ranges in summer even to the most remote arctic islands. Colonel Sabine notices it, in the appendix to Captain (now Sir Edward) Parry's 'First Voyage,' as the Musquito Hawk, and states that a female was found on Melville Island, lying dead on the ground about a quarter of a mile from the sea. He adds, that these birds are known to breed and inhabit as far north as Hudson's Bay; but as they live principally in woods, and feed on musquitoes and other winged insects, which are very rare in the North Georgian Islands, it is more than probable that the individual found dead was an accidental visitor, and had perished for want of food. It was extremely thin, but the plumage was in good preservation. Fabricius does not mention it, he observes in conclusion, as known in Greenland. Sir John Richardson states that its very peculiar noise is most frequently heard in the evening, and often seems to be made close to the listener, though the bird that produces it is so high in the air as to be nearly imperceptible. He describes this sound as resembling that produced by the vibration of a tense thick cord in a violent gust of wind, and says that the Pisk (the common name for the bird) considerably resembles some of the *Falconidæ* in its evolutions in the air. It often remains stationary, fluttering its wings rapidly, and then suddenly shoots off a long way by a gliding motion: at that moment the loud vibratory noise is heard. "It also traverses the air backwards and forwards, quartering the sky as regularly as the Hen Harrier surveys a piece of ground. The female deposits her eggs on the ground without making any nest, generally selecting the border of a cultivated field or an open glade in the forest, and during incubation sits so close that she may be almost trodden down. When any person approaches her the male sallies from the adjacent thicket and stoops at the intruder, passing within a foot or two of his head, then rising again and wheeling round to repeat the same manœuvre. In the meanwhile his mate flutters from the nest along the ground as if disabled, and hides herself at a short distance among the gray grass, from which she can hardly be distinguished. The Pisk makes its first appearance at Great Bear Lake generally about the last day of May, and was observed hatching on the Saskatchewan on the 8th of June. Its eggs are narrower than those of *Caprimulgus vociferus*, but of the same colours, rather differently distributed; they measure nearly 14 lines in length." ('Fauna Boreali-Americana.')

Pisk (*Chordeiles Americanus*).
Upper figure, male; lower figure, female, with an egg.

Sir John Richardson states the extreme northern range of this bird as 68° N. lat. (east of the Rocky Mountains, migratory), and he notices it as observed in the summer, when it is common, on the Saskatchewan, lat. 53° to 54° N., and from 600 to 1000 miles distant from the sea-coast; as very common in the vicinity of Philadelphia, lat. 40° N. (Bonaparte), but as not having its winter-quarters in the United States. It also appears in Sir John's list of species which summer or breed in the Fur Countries and in Pennsylvania, but winter farther to the southward. In Prince Bonaparte's 'Geographical and Comparative List,' the southern and central parts of North America are recorded as the localities of the species.

Scotornis (Sw.).—General structure of *Caprimulgus*; but the outer toe is shorter than the inner.

Sub-genera, *Scotornis.*—Rictus strongly bristled. Tail lengthened, graduated, or rounded. (Sw.)

S. climaturus, African Long-Tailed Night-Jar. Its size is rather smaller than that of *Macrodipteryx*, although, from the development of its tail, it is much longer. The bristles considerably exceed the length of the bill; the third quill is longest; the first is rather shorter than the fourth, while the fifth is $\frac{8}{10}$ths of an inch shorter than the fourth. The tail is very long, measuring from the base 9 inches, of which 3¼ inches are occasioned by the two middle tail-feathers exceeding the others; the outer lateral toe is shorter than the inner. The ground colour of the plumage is light ferruginous-brown varied with dark freckles. The chin and rictal stripe white; the lesser wing-coverts have at their tips a broad band of white, and the greater have a terminal spot of cream-colour, much smaller than the former. The ground colour of the five primary quills

is entirely black, without any rufous, their tips only being freckled with gray; but they are crossed in the middle by a snowy-white broad band beginning in the inner web of the first and terminating on the outer web of the sixth quill: the remaining quills are varied with black and rufous and tipped with white. The tail is variegated in the usual manner, the middle pair of feathers having about twenty very slender transverse bars, but much undulated, while the outer margin of the exterior feather, and the tips of that and of the next are pure white. No gray in the plumage. Total length, including tail, 13 inches. (Sw.)

It is a native of Africa, and is common in Senegal.

African Long-Tailed Night-Jar (*Scotornis climaturus*). (*Caprimulgus climaturus*, Vieill.)

Macrodipteryx (Sw.).—Rictus strongly bristled; wings long, equal to the tail, and with a lengthened reniform feather in each. Tail even.

M. Africanus, Pennant-Winged Night-Jar, or Long-Shafted Goat-Sucker. It has wings, for the small size of the bird, very long, rather exceeding, or at least equalling, the tip of the tail, which is quite even and consists of ten feathers. Of the first three quills, which are much the longest, the first is shorter than the third, which is slightly succeeded by the second. The long-shafted feathers are inserted immediately between the primary and secondary quills. The bristles of the mouth are strong and equal to the length of the bill, which is weak. The middle toe is lengthened, and the lateral toes are equal. Colour of the plumage mixed, as in others of the family. Upon each web of each of the primary quills is a row of nine rufous and nine black spots: the rufous bars become very small towards the tips, where the black predominates. The lesser quills are black, with four rufous bands, the tips black. The middle tail-feathers are gray, speckled with black points, and crossed by six black bars, all of which are irregular, excepting the last, which, as on all the other feathers, is regular, well defined, and placed just behind the tips; the outer web of the exterior feather is fulvous white, with about ten black spots, at equal distances from each other. Some of the scapulars have a broad cream-coloured stripe, which forms a connected series when the feathers lay over each other, but those which are conspicuous on the supposed female can scarcely be discerned in the male; this latter however has a few obscure white mottles on the chin, throat, and round the ears. Total length about 8 inches.

Mr. Swainson, from whose 'Birds of Western Africa,' the above description is taken, observes that the female is entirely destitute of the long-shafted or supplementary feathers. "Now this," says Mr. Swainson, "is a very important fact, for it goes far to prove that they are not essential to the economy of the species; for if otherwise, both sexes would possess them, unless it be contended, a supposition highly improbable, that the male feeds in one manner and the female in another. In the absence of all information upon this point, we are led to conclude that they are more ornamental than useful, given to the male sex as attractive decorations to the female, in a similar manner as the flowing feathers of the Paradise Bird are known to distinguish the male sex. Whether or no these ornamental plumes are lost after the season of incubation is a subject for future inquiry;

but they are certainly of very unequal lengths in different individuals. We have seen them in one bird only 7 inches long, while in that now before us they measure in extreme length 17 inches; the webs occupy exactly six, while all the rest of the shaft is naked, the rudimentary

Pennant-Winged Night-Jar, or Long-Shafted Goat-Sucker (*Macrodipteryx Africanus*). Male.

hairs on each side merely indicating the position of the laminæ, had they been developed. We cannot subscribe to an opinion we have heard expressed, that these latter have been rubbed or worn off.

Proïthera diurna.

Another specimen, which we suppose is the female, is perfect in all its plumage, but has no indication, as already observed, of these feathers. In their texture they are remarkably flexible, moving about with the least breath of wind. The inner web is so broad, that the laminæ in the middle measure 2½ inches; the outer web, on the contrary, is very narrow, and the longest laminæ are hardly half an inch."

This is the *Caprimulgus Macrodipterus* of Afzelius, and the *Caprimulgus longipennis* of Shaw.

It is a native of Sierra Leone, Africa.

Proïthera (Sw.).—Rictus almost smooth; wings very long, equal to the tail, which is short and even; tarsus very naked.

P. diurna (*Caprimulgus diurnus*, Wied., *Nacunda*, Temm.). The plumage of the female is above a mixture of gray-brown, yellowish-red, and brownish-black, marked with great spots of blackish-brown, with wide borders of yellowish-red; chin pale-yellow, striped with gray-brown; tail marbled with brownish-black and bright-yellow, with nine or ten transverse bands speckled with brownish-black. Plumage beneath white lineated with gray-brown; middle of the belly white, spotless. Length rather more than 10 inches.

It is a native of Brazil and Paraguay.

GOAT'S-THORN. [ASTRAGALUS.]

GOAT-WEED. [ÆGOPODIUM.]

GO'BIO, a genus of Fishes belonging to the section *Malacopterygii Abdominales* and family *Cyprinidæ*. The species of this genus differ chiefly from the true Carps in having the anal and dorsal fins short and destitute of bony rays. *G. fluviatilis* (Ray), the Common Gudgeon, affords the best example of this genus.

The Gudgeon is a British fish, and is found in many streams that in their course flow over gravelly soils. The Thames, Mersey, Colne, Kennet, and Avon, produce fine Gudgeons. They swim together in shoals, feeding on worms, aquatic insects, and their larvæ, small molluscous animals, ova, and fry. They afford ample amusement to those sportsmen who are satisfied with numbers rather than weight. The Gudgeon rarely exceeds 8 inches in length. It spawns in May, and the young are about an inch long in August.

GO'BIUS, a genus of Acanthopterygious Osseous Fishes belonging to the family *Gobioidæ*. All the species have two dorsal fins, scaly bodies, and a disc beneath the throat formed by the united ventral fins. By means of this disc they have the power of attaching themselves to rocks. Several species of Goby are met with on the British coast. The largest is the *Gobius niger* of Linnæus, which attains the length of 6 inches, and ranges from Cornwall to the Orkneys. Mr. Couch has inquired into the habits of the Black Goby, and finds that when it has seized its prey it carries it off alive in its mouth to its resting-place, which is among rocks. The other British Gobies, *G. bipunctatus*, *G. minutus*, *G. gracilis*, and *G. unipunctatus*, are mostly inhabitants of sandy ground. On the shores of the Mediterranean Gobies abound, and are also found in deep water, even to a depth of 50 fathoms. The deep-water species are distinct from those frequenting the coast-line.

The species of *Gobius* are very tenacious of life, and are capable, like their neighbours, the Blennies, of living some time out of water. The most remarkable fact connected with the history of these fishes is their nidification. That the Goby built a nest was known to the ancient Greeks. This nest they construct in spring, of seaweeds, &c., and in it the female deposits her eggs, whilst the male watches over them until they are hatched. The nest of the Goby is very well built, and has of late been observed on our own coasts. True Gobies occur in the seas of the southern hemispheres as well as in those of the northern.

GOBY. [GOBIUS.]

GODWIT. [SCOLOPACIDÆ.]

GOLD, one of the precious metals. It differs remarkably from other metals, with a very few exceptions, in the fact that it is found in nature in its metallic state. It is occasionally found mineralised by tellurium. Native gold is Monometric, and occurs in cubes without cleavage, also in grains, thin laminæ, and masses, sometimes filiform or reticulated. The colour varies in shade, sometimes being a bright yellow, at others almost silvery-white, from the quantity of silver with which it is mixed. It is very ductile and malleable. Hardness 2·5 to 3. Specific gravity 12 to 20, varying according to the metals alloyed with the gold. Native gold usually contains silver, and in very various proportions. The finest native gold from Russia yielded—gold 98·96, silver 0·16, copper 0·35, iron 0·05; specific gravity 19·099. A gold from Marmato afforded only 73·45 per cent. of gold, with 26·48 per cent. of silver: specific gravity 12·666. This last is in the proportion of 3 of gold to 1 of silver. The following proportions have also been observed:—3½ to 1, 5 to 1, 6 to 1, 8 to 1; and this is the most common; 12 to 1 also is of frequent occurrence.

Copper is often found in alloy with gold, and also Palladium and Rhodium.

A Rhodium Gold from Mexico gave the specific gravity 15·5 to 16·8, and contained 34 to 43 per cent. of rhodium.

Iron and copper pyrites are often mistaken for gold by those inexperienced in ores. Gold is at once distinguished by being easily cut in slices and flattening under a hammer. The pyrites when pounded are reduced to powder: iron pyrites is too hard to yield at all to a knife, and copper pyrites affords a dull greenish powder. Moreover the pyrites give off sulphur when strongly heated, while gold melts without any such odour.

Native Gold is to a large extent obtained from alluvial washings. It is also found disseminated through certain rocks, especially quartz and talcose rocks, and it is often contained in pyrites, constituting the auriferous pyrites; the detritus affording gold-dust has proceeded from some gold-bearing rocks.

Gold is widely distributed over the globe. It occurs in Brazil (where formerly a great part of that used was obtained), along the chain of mountains which runs nearly parallel with the coast, especially near Villa Rica, and in the province of Minas Geraes; in New Granada, at Antioquia, Choco, and Grion; in Chili; sparingly in Peru and Mexico; in the southern of the United States. In Europe it is most abundant, in Hungary, at Königsberg, Schemnitz, and Felsobanya, and in Transylvania, at Kapnik, Vorospatak, and Offenbanya; it occurs also in the sands of the Rhine, the Reuss, and the Aar; on the southern slope of the Pennine Alps, from the Simplon and Monte Rosa to the valley of Aosta; in Piedmont; in Spain, formerly worked in Asturias; in the county of Wicklow in Ireland; and in Sweden at Edelfors. In the Ural Mountains there are valuable mines, also in the Cailles Mountains in Little Tibet. There are mines in Africa at Kordofan, between Dar-fur and Abyssinia; also south of Sahara, in the western part of Africa from Senegal to Cape Palmas; also along the coast opposite Madagascar, between 22° and 23° S. lat., supposed to have been the Ophir of the time of Solomon. Other regions in which gold is found are China, Japan, Formosa, Ceylon, Java, Sumatra, and the Philippines.

Until lately nearly all the gold of commerce came from Asiatic Russia and Mexico, but recent discoveries of gold in California and Australia have opened new and vast sources of supply.

From 1600 to 1700 the entire supply of gold for Europe was obtained from America, whose mines are estimated in the one hundred years to have produced 337,500,000*l.* worth of the precious metal. During the 18th century the supply of gold and silver was still mainly derived from the Americas, the great mine of Valenciana, producing 125,000*l.* sterling per annum for 40 years, and the district of Zaccatecas adding largely to the amount, although these were rapidly failing towards the end of the century. A great increase of gold was produced from the mines of Russia, which are still very productive; they are principally alluvial washings, and these washings seldom yield more than 65 grains of gold for 4000 lbs. of soil, never more than 120 grains. The alluvium is generally most productive, where the loose material is most ferruginous. The mines of Ekaterinburg are in the parent rock—a quartz constituting veins in a half-decomposed granite called Beresite, which is connected with talcose and chloritic schists. The shafts are sunk vertically in the beresite, seldom below 25 feet, and thence lateral galleries are run to the veins. These mines afforded between the years 1725 and 1841 679 poods of gold, or about 30,000 lbs. troy. The whole of the Russian mines yielded in 1842, 970 poods of gold, or 42,000 lbs. troy, half of which was from Siberia, east of the Urals. In 1843 the yield was nearly 60,000 lbs. troy; in 1845, 62,000 lbs. troy; and in 1846, 75,353 lbs.

In the five following years to 1851 nearly 296,932 lbs. troy weight of gold have been raised in Russia.

At the Transylvania mines the gold is obtained by mining, and these mines have been worked since the time of the Romans. The annual yield of Europe exclusive of Russia is not above 250,000*l.* The sands of the Rhône, Rhine, and Danube contain gold in small quantities. The sands of the richest quality contain only about 56 parts of gold in 100,000,000. Sands containing less than half this proportion are worked. Africa yields annually at least 4500 lbs. troy, and Southern Africa 1250 lbs. The mines of the United States have lately produced about 1,000,000 dollars a year.

In South America the gold region of California extends along the valley of the Sacramento and the valley of San Joaquin, immediately south. The gold occurs in flattened grains, or scales, and occasionally in lumps of large size. The yield is enormous. The amount received at the mint in the United States in 1851 was at the rate of 32,000,000 dollars a year. The aggregate production of gold in South America does not appear to have increased within the last five years. The rate of produce in the Australian mines is as follows:—The Sydney district produced from 29th May 1851 to 31st October 1851, 67,152 oz. gold, value 214,886*l.*, or to November 1851, 79,340 oz. gold, value at 257,855*l.* 7*s.*, and to December 31, 142,975 oz. gold, value 464,668*l.* 15*s.* In the Victoria district to the end of December 1851, Ballarat produced 25,108 oz., value 75,324*l.*; Mount Alexander, 30,007 oz., value 96,021*l.* In December there was shipped from Victoria 145,116 oz., on the 8th January, 75,188 oz. Only about two-fifths of the gold realised is sent by the Government escort, hence there is much difficulty in arriving at the actual amount. But the imports to this country may be safely relied on as representing the maximum produce of our colonial gold-fields, and the auriferous districts of America.

From November 1850 to June 1851 the Bank of England issued 9,500,000 sovereigns, being at the rate of 18,000,000 a year, and so great is the increasing demand for gold coins, that the rate of production can scarcely keep pace with it.

It may be interesting to know that from the account kept at the Bank when the light coin was called in, in 1842, that 12,000,000*l.* were received light, and 36,000,000*l.* still circulated of full weight; 40,000,000*l.* may therefore be regarded as the quantity of gold coin in circulation, allowing from 3 to 4 per cent. for the natural wear of the coin. The following table gives over an extended period the

Coinage of Great Britain.

Reign of	No. of Years.	Gold.	Silver.	Total.
James I.	22	3,666,389	1,807,277	5,473,666
Charles I.	35	3,465,188	9,776,544	13,241,732
Charles II. . . .	22	4,177,253	3,722,180	7,899,433
James II.	4	2,113,638	2,115,115	4,228,753
William and Mary . .	12	2,314,889	7,093,074	9,434,963
Anne	13	2,484,531	618,212	3,102,743
George I. . . .	14	8,492,876	233,045	8,725,921
George II.	37	11,662,216	304,360	11,966,376
George III. . . .	61	75,753,443	6,996,765	82,750,206
George IV.	9	36,147,700	2,216,168	38,363,868
William IV. . . .	7	14,600,000	2,800,000	(?)
Victoria, 1837 to 1841 . .	4	4,991,210	889,102	5,880,312
Victoria, 1842 to 1847 .	5	29,886,457	2,440,614	32,277,071

Total coinage of 32 years ending 1847:—Gold, 90,029,383*l.*; Silver, 13,390,000*l.*; Copper, 248,210*l.*

A large quantity of gold is consumed every year in arts and manufactures, and thus regularly removed from the stock of our circulating wealth. In Birmingham not less than 1000 oz. of fine gold are used every week, and the weekly consumption of gold leaf is as follows:—

	Ounces.
London	400
Edinburgh	35
Birmingham	70
Manchester	40
Dublin	12
Liverpool	15
Leeds	6
Glasgow	6
Total	584 weekly,

of which not one-tenth can be recovered. For gilding metals by the electrotype and the water-gilding processes not less than 10,000 oz. of gold are required annually. One establishment in the Potteries employs 3500*l.* worth of gold per annum, and nearly 2000*l.* worth is used by another. The consumption of gold in the Potteries of Staffordshire for gilding porcelain and making crimson and rose-colour varies from 7000 to 10,000 oz. per annum.

The Indus and the Euphrates were the earliest spots whence man obtained the precious metal gold—Nubia and Ethiopia on the south, and Siberia on the north next opened out their auriferous treasure to gratify human necessity and to indulge human luxury. Europe then began to unfold her golden stores, and Illyria and the Pyrenees, together with the land of the Hungarians and many parts of Germany to the Rhine, were sought successfully for gold. Our islands yielded something to the store, and then the New World of the Americans opened by Columbus a source from which the Old World was to supply its golden waste. On and on still westward rolled the golden ball, until at length it rested in California; Europe and Asia rush equally to that new El Dorado, and the man of China is found at the side of the English gold streamer. Then, as if to double the girdle, the islands of the Pacific and our own Australia open their exceeding stores. (Hunt.)

Australia is undoubtedly the most important gold-bearing district in relation to Great Britain. Her shores are now being crowded with emigrants from the mother country seeking the precious metal, and in proportion to her population she is now undoubtedly, in this point of view, the richest country of the world. For the purpose of guiding those who are seeking Australia on account of its gold, the professors of Natural Science, in the Museum of Practical Geology, delivered a course of lectures in the summer of 1852. These lectures were as follows:—

1. 'The Geology of Australia, with Especial Reference to the Gold Regions,' by J. Beete Jukes, M.A. F.G.S., Local Director of the Geological Survey of Ireland; author of 'Sketch of the Physical Structure of Australia.'

2. 'On our Knowledge of Australian Rocks as derived from their Organic Remains,' by Edward Forbes, F.R.S.

3. 'The Chemical Properties of Gold, and the Mode of Distinguishing it from other Substances resembling it,' by Lyon Playfair, C.B. F.R.S.

4. 'The Dressing or Mechanical Preparation of Gold Ores,' by W. W. Smith, M.A. F.G.S.

5. 'The Metallurgical Treatment and Assaying of Gold Ores,' by John Percy, M.D. F.R.S.

6. 'The History and Statistics of Gold,' by Robert Hunt, keeper of Mining Records.

We subjoin an account of the auriferous rocks of Australia from the lecture of Mr. Jukes:—

"Sir R. Murchison, in his address to the Geographical Society in 1844, alluded to the possibly auriferous character of the Great Eastern Chain of Australia, being led thereto by his knowledge of the auriferous chain of the Ural, and by his examination of Count Strzelecki's specimens, maps, and sections. Some of Sir R. Murchison's observations having found their way to the Australian papers, a Mr. Smith, at that time engaged in some iron works at Berrima, was induced by them in the year 1849 to search for gold, and he found it. He sent the gold to the Colonial government, and offered to disclose its locality on payment of 500*l.* The governor however not putting full faith in the statement, and being, moreover, unwilling to encourage a gold fever without sufficient reason, declined to grant the sum, but offered, if Mr. Smith would mention the locality, and the discovery was found to be valuable, to reward him accordingly. Very unwisely, as it turns out, Mr. Smith did not accept this offer; and it remained for Mr. Hargraves, who came with the prestige of his Californian experience, to re-make the discovery, and to get the reward from government on their own conditions.

"This first discovery was made in the banks of the Summer Hill Creek and the Lewis Ponds River, small streams which run from the northern flank of the Conobalas down to the Macquarrie. The gold was found in the sand and gravel, accumulated especially on the inside of the bends of the brook, and at the junction of the two water-courses, where the stream of each would be often checked by the other. It was coarse gold, showing its parent site to be at no great distance, and probably in the quartz veins traversing the metamorphic rocks of the Conobalas. Mr. Stutchbury, the government geologist, reported on the truth of the discovery, and shortly afterwards found gold in several other localities, especially on the banks of the Turon, some distance north-east of the Conobalas. This was a much wider and more open valley than the Summer Hill Creek, and the gold accordingly was much finer, occurring in small scales and flakes. It was however more regularly and equably distributed through the soil, so that a man might reckon with the greater certainty on the quantity his daily labour would return him. At the head of the Turon River, among the dark glens and gullies in which it collects its head waters, in the flanks of the Blue Mountains, the gold got 'coarser,' occurring in larger lumps or nuggets, but these being more sparingly scattered. The reason of these circumstances, which are common to all auriferous regions, has been given in the former part of this Lecture when speaking of the power of moving water.

"With the subsequent history of the 'gold diggings' of Australia, the discovery of many rich auriferous districts, both in New South Wales and Victoria, you must all be more or less familiar.

"In Mr. Arrowsmith's map, appended to the Parliamentary Report just issued, all the auriferous spots are marked in yellow. They occur at intervals along the flanks of the Great Eastern Chain, or on its lateral spurs and subordinate ranges through an extent of country about 1000 miles in length, about as far as from London to Gibraltar or the confines of Turkey, or as from London to Iceland in a straight line. The principal localities marked on this map are Grafton Range and Burnet River, north of the Condamine; Stanley Creek and Canning Downs in the Moreton Bay district; several spots in the neighbourhood of Liverpool Plains; the Turon and Conobalas on the Macquarrie, below Bathurst; the Abercrombie River at the head of the Lachlan; some spots on each side of Breadalbane Plains; the Braidwood and Araluen diggings in the Shoalhaven district; Lake Eimeo in the Australian Alps; and Ballarat, and Mount Alexander and Mount Blackwood, north-west of Port Philip.

"In every one of these localities granite and metamorphic rocks occur, and quartz veins are frequently spoken of. This is an important fact to bear in mind.

"In scarcely any of them do we find mention made of the gold being seen in the actual rock, but in the drift clay, sand, and gravel, or lying loose on the surface of the ground. The hundredweight of gold, indeed, found by Dr. Ker north of Bathurst, is described as a block of highly auriferous quartz, lying among a lot of other loose blocks, evidently derived from a broad quartz vein running up the hill behind them. Such a mass, indeed, could hardly be transported far from its original site by any conceivable current of water.

"The superficial drift in which the diggings have been carried on varies in thickness from a few inches to 20 or 30 feet. The following is an extract from a lecture given by a Mr. Gibbon, in Melbourne, and reported in the 'Melbourne Argus,' giving an account of the Ballarat diggings:—'On the surface of the earth was turf in a layer of about a foot thick, below which was a layer of rich black alluvial soil, and below that gray clay; below that again was a description of red gravel, which was sometimes very good; then red or yellow clay, in which gold was found; and then a stratum, varying in thickness, of clay streaked with various colours, and scarcely worth working; and the next stratum was of hard white pipe-clay, which was a decided barrier. Immediately above it however was a thin layer of chocolate-coloured clay, tough and soapy. This was the celebrated blue clay, and was very rich.

"'The ground on which the diggings were situated was a sloping bank. The blue clay is found near the surface on the brow of the hill, that is, at the depth of about a foot; but it is sometimes necessary to dig 20 feet before arriving at it.'

"Mr. Latrobe, governor of Victoria, describes the Ballarat diggings as carried on through—

"'1. Red ferruginous earth and gravel.

"'2. Streaked yellowish and red clay.

"'3. Quartz gravels of moderate size.

"'4. Large quartz pebbles and boulders; masses of ironstone set in very compact clay, hard to work.

"'5. Blue and white clay.

"'6. Pipe-clay.

"'In some workings the pipe-clay may be reached at the depth of 10 or 12 feet, in others not at 30 and upwards.'

"To enter farther into the details of the several diggings would be alike tedious and useless. I must refer you for them to the two Parliamentary Reports published, the one in February and the other in June, and to the many small publications with which the shops are now swarming.

"My object to-night has been to give you such a rough sketch of the geology of Australia, and of the geological facts and principles that ought to guide any one in his search after gold, as may be of use to those intending to emigrate there.

"In conclusion, I may perhaps be allowed to utter one word of advice.

"Gold-digging is very hard work—just such work as you see navigators at in a railway cutting, or brick-makers in a brick-pit. You must work hard all day, lie hard all night, with but little shelter, often with scanty food, and with nothing of what you have probably been accustomed to consider necessary comfort. If you find you have no luck at the diggings, or if your health, or strength, or resolution fail you, do not therefore give up or despond altogether. You go out to dig for gold; do not be ashamed to dig for anything else. I speak to those now who have been hitherto unaccustomed to manual labour. Recollect, it is the avowed object of your voyage, and the only thing you have to trust to. If you fail to dig up gold there are lands to be ploughed, sheep to be herded and sheared, cattle to be tended, corn to be sown and reaped—every one of these fully as honourable occupations as digging for gold. Go, then, with a bold and resolute heart, determined to get your living by the strength of your own arms and the sweat of your own brows; and be assured, that industry and perseverance lead to fortune in Australia with fewer impediments and uncertainties in the way than in any part of the world."

Since the above was written, other districts in Australia have yielded the precious metal, and every day is adding to our knowledge of the wide extension of this metal on the surface of the earth. A few months ago it was announced that gold had been discovered at the Cape of Good Hope; and at the beginning of the present year the late Dr. Stanger delivered a lecture at Natal, in which he pointed out the probability of gold being found in the neighbourhood of that colony. For an account of the Salts of Gold, and its applications in the arts and sciences, see GOLD, in ARTS AND SC. DIV.

(*Lectures on Gold delivered at the Museum of Practical Geology;* Dana, *Manual of Mineralogy.*)

GOLD-CARP. [CYPRINIDÆ.]

GOLDFINCH. [CARDUELIS.]

GOLDFINNY. [CRENILABRUS.]

GOLD-FISH. [CYPRINIDÆ.]

GOLD OF PLEASURE. [CAMELINA.]

GOLDSINNY. [CRENILABRUS.]

GOLT, or GAULT, an argillaceous deposit, separating the upper greensand (also called firestone, malm-rock, &c.) from the lower greensand (also called Woburn sand, iron-sand, &c.). In Kent, Sussex, Surrey, the Isle of Wight, Wiltshire, and Cambridgeshire its geological situation and organic contents may be well studied. The clay of Specton, on the Yorkshire coast, unites the characters of Golt and Kimmeridge Clay. [CHALK FORMATION.]

GOMPHOLITE, a name given by M. Brongniart to conglomerate rocks of the Tertiary series, which in Switzerland are called Nägelflue.

GOMPHONEMA. [DIATOMACEÆ.]

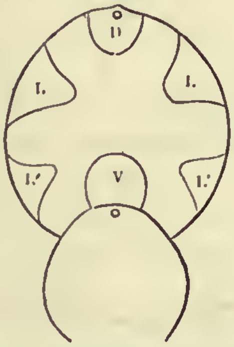
GONGYLOPHIS. [BOIDÆ.]

GONIATITES, an extinct group of fossil shells, belonging to the division of Cephalopodous *Mollusca.* The species which it contains are usually arranged, by writers on organic remains, as a section of Ammonites; but their appropriate characters were never completely given till M. Von Buch, following Haan of Leyden, published his 'General Essay on the Sutures of Ammonites' (read to the Academy of Sciences at Berlin in April, 1830; translated in the 'Annales des Sciences Naturelles,' 1833).

The families or genera of *Nautili* and Ammonites are seldom well understood by the conchological student, because the real distinctions between them are not the most apparent. The most constant of all the characters of Ammonites is the situation of the siphon, which, instead of perforating the disc of the transverse internal plates as in *Nautilus,* touches and lies parallel to the inner face of the shell on the dorsal line. There is another obvious and generally complete distinction in the form of the sutures, or intersections of the transverse internal plates (septa) with the inner surface of the shell. In Ammonites this suture is undulated or angularly bent into lobes and sinuses; in *Nautilus*, even or gently waved. The exceptions to this are few, but remarkable. *Nautilus ziczac* of Sowerby (Dr. Buckland's 'Bridgewater Treatise,' pl. xliii. fig. 3) has sutures waved as much as some true Goniatites, and there is in fact every degree of sinuosity in the edges of the septa of the nautiloid and ammonitic families.

M. Von Buch supposes the sinuous edges of the septa of Ammonites to be necessarily derived from the dorsal position of the siphuncle. "All the other differences," says he, "are derived from this capital distinction. The *Nautilus*, which passes a very large siphon through the middle of the septa, appears sufficiently attached by this membrane to the basis on which it rests. There is no need of any other support, and the septa remain in general smooth and concave without sinuosities on the edges. The small dorsal siphon of the Ammonites would not suffice to secure the animal from displacement on the surface of its cell." Other supports are necessary, and they are found in the marginal lobes which the form of the animal impresses on the partitions of the chambers. These are generally six in number; one ventral V, one dorsal D, and two on each side L, L'. (See *fig.* 1; and Dr. Buckland's 'Bridgewater Treatise.')

Fig. 1.



M. Von Buch, viewing Goniatites as a section of Ammonites, presented the following characters of the group in 1830:—

The lobes of the septa are completely deprived of lateral denticulations or symmetrical crenatures, so that their contour presents always a continuous uninterrupted line. The siphon, compared to that of other Ammonites, is small and delicate; the striæ of growth are sigmoidal on the sides (as in *fig.* 2), inflexed from the aperture on the back, so as to form a sinus there in the aperture, thus resembling *Nautili;* whereas in Ammonites generally the striæ advance along the dorsal line supported probably by the siphon. The last chamber of Goniatites extends, according to Count Münster, more than one turn beyond the concamerations, but in Ammonites only three-fourths of a turn.

Later investigations have scarcely modified these fundamental views, except by showing a greater variety in the forms of the sutures than was at first expected.

Eighteen species of Goniatites are distributed by Von Buch in the following manner:—

Sutures with rounded lobes:—
- *a.* Dorsal lobe simple . . . . . . 4 species.
- *b.* Dorsal lobe double . . . . . 1 species.

Sutures with pointed lobes:—
- *a.* Dorsal lobe simple . . . . . . 6 species.
- *b.* Dorsal lobe double . . . . . 7 species.

Count Münster ('Ann. des Sci. Nat.,' 1834) gives 22 ascertained and 4 doubtful species (mostly different from Von Buch's) from the Fichtel-Gebirge. His arrangement is different, namely:—

1. With simple lobes slightly sinuous and rounded . . . . 4 species.
2. With angular or linguiform lobes:—
   - *a.* Shell entirely involute, sutures with one lateral angular lobe . . . . . 8 species.
   - *b.* Shell entirely involute, sutures with two lateral lobes . . . . 4 species.
   - *c.* Shell evolute, three lateral lobes . . 6 species.

Doubtful species . . . . 4 species.

Martin, in 'Petrificata Derbiensia,' 1809, figured two species of Goniatites; Sowerby, in the 'Mineral Conchology of Great Britain,' added two others; and Professor Phillips, in the second volume of the 'Illustrations of the Geology of Yorkshire,' 1836, has raised the number of British species from the carboniferous limestone, millstone-grit, and coal-formations, to 33 species, the septa of which are completely ascertained.

Beyrich ('De Goniatitis in Montibus Rhenanis Occurrentibus,' 1837) describes 18 species (8 of them supposed to be new), and presents a general classification of all the Continental species supposed to be distinct, at that time known by the descriptions of Haan, Von Buch, Münster, Goldfuss, &c. The number of species of Goniatites at present known is about 150.

In external form Goniatites present an almost complete series of gradations from the involute sub-globular figure, common among *Nautili*, to the discoid spiral shape of the flattest Ammonites. The following figures, from Phillips's 'Geology of Yorkshire,' vol. ii. pl. 19 and 20, will illustrate this:—

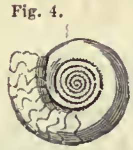
Fig. 2.

Goniatites truncatus. (Phillips.)

Fig. 3.

Goniatites Listeri. (Sowerby.)

Fig. 4.



Goniatites spirorbis. (Phillips.)

Fig. 5.

Goniatites Gibsoni. (Phillips.)

Most of the Goniatites have rounded backs; a few are carinated, as *G. vittiger* and *G. rotiformis*, Phillips.

In nearly all the Goniatites the surface is marked by transverse sigmoidally-bent lines of growth; a few have merely annular striæ; in some these striæ rise into tubercles on the inner edge of the whorls (*G. Listeri*, Sow.; *G. subnodosus*, Münst.). The striæ are occasionally reticulated by spiral lines. Radiating undulations occur on some of the flatter species; in a few (*G. Gibsoni*) there are ribs divided after the manner of many Ammonites; and *G. binodosus*, Münster, has two rows of tubercles. In all these particulars the parallelism of the series of Goniatites to that of common Ammonites is very remarkable.

This analogy with the usual forms of Ammonites is augmented by the occurrence of constrictions on the cast of the interior of the shells. (*Fig.* 3, *c.*) These constrictions, corresponding to internal thickenings of the shell, are most remarkable in the involute Goniatites. (See Phillips's 'Geology of Yorkshire,' vol. ii. pl. xix. fig. 1, 2, 24, 26; pl. xx. fig. 1; Münster, in 'Ann. des Sci. Nat.,' pl. v. fig. 2; and Beyrich, in his 'Dessertation,' tab. ii. fig. 8.) They are parallel or nearly so to the lines of growth, and cross the sutures without any definite relation. They may be viewed as periodical thickenings of the edge of the aperture, and as contributing to strengthen the last chamber of the enlarging shell. They vary as to number and position in individuals of the same species. The aperture of many Goniatites resembles that of the recent *Nautilus Pompilius*.

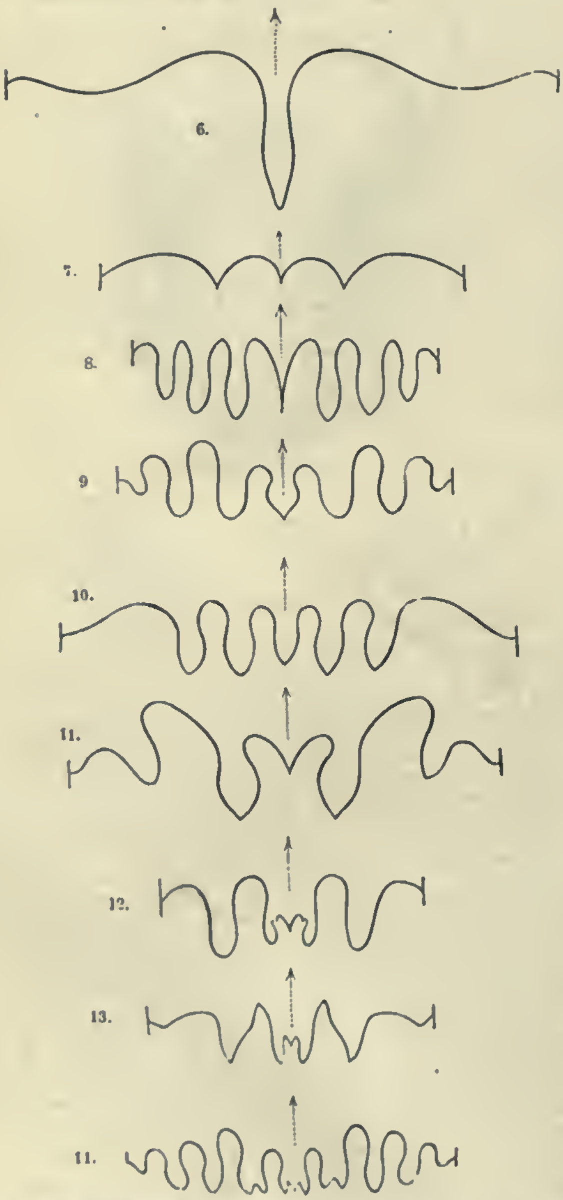
The sutures of the Goniatites are extremely various, beautiful, and characteristic of the species. Individuals of several of the species have been compared almost from the nucleus to full growth without any great change being visible in the form of the septum (as for instance, *G. Listeri*), but in others this is not the case. The following arrangement and accompanying figures will show the principal variations of the sutures. The arrow is in each case supposed to point towards the aperture.

Division 1. The dorsal lobe simple; one lateral lobe.
- *a.* Lateral lobe single and rounded. *G. expansus*, Von Buch, *fig.* 6.
- *b.* Lateral lobe single and angular. *G. sublævis*, Munster, *fig.* 7.

Division 2. The dorsal lobe simple; more than one lateral lobe.
- *a.* Lateral lobes linguiform, and nearly equal. *G. Henslowi*, Sowerby, *fig.* 8.
- *b.* Lateral lobes rounded and nearly equal. *G. serpentinus*, Phillips, *fig.* 9.
- *c.* Inner lateral lobes very much the largest. *G. Munsteri*, Von Buch, *fig.* 10.
- *d.* Lateral lobes very unequal and oblique. *G. Hœninghausi*, Von Buch, *fig.* 11.

Division 3. Dorsal lobe divided; lateral lobe single.
- *a.* Lateral lobes and sinuses rounded. *G. bidorsalis*, Phillips, *fig.* 12.
- *b.* Lateral lobes and sinuses angular. *G. striatus*, Sowerby, *fig.* 13.

Division 4. Dorsal lobe divided or complicated; lateral lobes more than one.
- *G. cyclolobus*, Phillips, *fig.* 14.



The same transition rocks which contain a large portion of the continental species of Goniatites yield a cognate group, from which they are with difficulty distinguished. These were first separated by Count Munster, under the name of *Clymenia*. If Goniatites are considered as of the ammonoid, *Clymeniæ* may be included in the nautiloid type. Their siphon is always on the inner margin, and the septa, instead of a reflex wave on the dorsal line, have there a bend forward toward the aperture. The *Clymeniæ* have all the same variations of form and surface which have been mentioned with regard to Goniatites. *Figs.* 15 to 18 represent the forms of septa of *Clymeniæ*, for comparison with those of Goniatites.

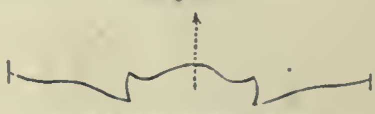
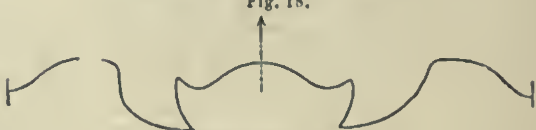
Clymenia compressa. (Münster.)

Fig. 17.



Clymenia planorbiformis. (Münster.)

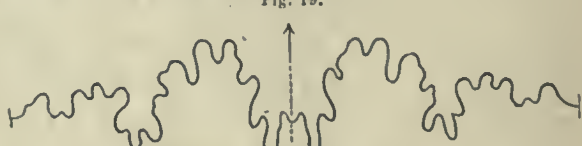
Fig. 18.



Clymenia striata. (Münster.)

Compared with ordinary Ammonites, the differences of the sutures are easily seized; but by the group of *Ceratites* of Haan, which is supposed to be peculiar to the muschelkalk, the transition is not difficult, as the subjoined figures show.

Fig. 19.



Ammonites planicostatus. (Sowerby.)

Fig. 20.

Ceratites nodosus, var.

Goniatites, and their allies, the *Clymeniæ*, appear entirely confined to the rocks of the carboniferous and older systems of strata. Only one species (*Goniatites Listeri*, Sowerby) is mentioned as occurring in the coal-formation, and that in the lowest portion (near Bradford, Halifax, and Sheffield, Yorkshire).

In the strata presumed to lie below the old red-sandstone occur many other species; at least so is the fact on the continent of Europe, though in Great Britain and Ireland they are but rarely met with in the primary and transition strata.

The Goniatites yet described are almost entirely from European localities. Von Dechen quotes *G. Listeri* from India. ('Handbuch der Geognosie.') None are mentioned in the slaty rocks of Westmoreland or Wales; none occur in the Silurian Rocks: they are not rare in Devonshire (occurring about Barnstaple and near Launceston). It is in the North of England, from Derbyshire to the Tweed, and in the limestones of the carboniferous system of strata, that they specially abound. About Enniskillen, and near Castleton, in the Isle of Man, the same rocks yield a considerable number of species.

The following is a list of the British species as given in Tennant's 'British Fossils,' 1847:—

Carboniferous Group.

Goniatites bidorsalis, Phil.	*G. carina*, Phil.
G. biferus, Phil.	*G. crenistria*, Phil.
G. Brownii.	*G. cyclolobus*, Phil.
G. calyx, Phil.	*G. discus.*

G. dorsalis, Brown.
G. evolutus, Phil.
G. excavatus, Phil.
G. expansus, Buck.
G. fasciculatus.
G. foraminosus, Phil.
G. Gibsoni, Phil.
G. Gilbertsoni, Phil.
G. granosus, Portl.
G. Henslowi, Sow.
G. implicatus, Phil.
G. intercostalis, Phil.
G. intermedius, Brown.
G. jugosus, Brown.
G. Kenyoni, Brown.
G. latus.
G. Listeri, Sow.
G. Longthorni, Brown.
G. Loonoyi, Philips.
G. mixonotus, Philips.
G. minutissimus, Brown.
G. mixolobus, Phil.
G. mutabilis.
G. nitidus, Phil.
G. obtusus, Phil.
G. paradoxicus, Brown.
G. parvus, Brown.
G. paucilobus, Phil.
G. platylobus, Phil.
G. proteus, Brown.
G. reticulatus, Phil.
G. rotiformis, Phil.
G. serpentinus, Phil.
G. Smithii, Brown.
G. sphæricus, Sow.
G. sphæroidalis.
G. spirorbis, Phil.
G. splendidus, Brown.
G. stenolobus, Phil.
G. striatus, Phil.
G. striolatus, Phil.
G. subsulcatus, Brown.
G. truncatus, Phil.
G. undulatus, Brown.
G. vesica, Phil.
G. vittiger, Phil.

Devonian Group.

Goniatites biferus, Phil.
G. carbonarius, Sow.
G. crenistria, Phil.
G. excavatus, Phil.
G. globosus, Münst.
G. inconstans, Phil.
G. insignis, Phil.
G. linearis, Münst.
G. mixolobus, Phil.
G. serpentinus, Phil.
G. spiralis, Phil.
G. spirorbis, Phil.
G. transitorius, Phil.
G. vinctum, Sow.

GONIODUS. [Squalidæ.]

GONIO'GNATHUS, a genus of Fossil Cycloid Fishes, from the London Clay. (Agassiz.)

GONIO'PHORUS (Agassiz), a genus of Fossil *Echinida*, from the Greensand. (Morris, *Catalogue*.)

GONIOPORA. [Madreporæa.]

GONOPLACIDÆ, *Gonoplacians*, an order of Brachyurous Crustaceans, whose carapace is either square or rhomboidal, and much wider than it is long. The posterior border, measured between the base of the fifth pair of feet, equals, nearly always, the half of its transverse diameter; while in the tribe of Ocypodians, as well as in the Cyclometopes, and the greater part of the *Oxyrhynchi*, the length of this border is only about a fourth of the greatest width of the carapace. The front is but little inclined, and very wide; it does not curve downwards so as to unite itself throughout nearly its whole width to the epistome, as in the Ocypodians, and it is equal to two-thirds of the buccal frame measured at the point of its greatest width. The ocular peduncles are in general very much elongated and rather small; their length often equals five or six times that of their diameter, and the cornea which terminates them is always small. The external angle of the orbit ordinarily occupies the lateral extremity of the carapace. The internal antennæ are always horizontal, quite exposed, and lodged in little pits (fossettes) distinct from the orbits. The external antennæ are disposed nearly as in the Ocypodians. The epistome is often placed at some distance behind the inferior orbitary border, a character which is always met with in the Cyclometopes, and exists but rarely in the family of Catametopes. The buccal frame is generally wider at its anterior border than at its posterior part, and the fourth joint of the external jaw-feet is inserted nearly always at the internal angle of the preceding articulation. The sternal plastron is very wide, and is sometimes perforated for the passage of the intromissive male organs (les verges); but in general these organs are inserted, as in other families, at the basilary joint of the posterior feet, and are lodged in a small transversal canal hollowed in the sternal plastron at the point of union of its two last segments, a canal which serves them for a sheath till they arrive under the abdomen. The length of the anterior feet varies; it is sometimes very considerable, and those of the third or fourth pair, which are always the longest among the eight last, have nearly two and a half times the length of the post-frontal portion of the carapace: they are all slender, and terminated by a styliform tarsus. The abdomen of the female is very wide, and covers nearly the whole of the sternal plastron; but that of the male, on the contrary, is very narrow, and instead of extending to the basilary joint of the posterior feet, leaves exposed a considerable portion of the sternal plastron between its external edge and the base of those feet. In the greater number of cases its second ring is entirely linear, while the others are sufficiently well developed.

Such is the character given to this tribe by M. Milne-Edwards, who places it between the Ocypodians and the Grapsoidians, and divides it into the four following genera:—

Pseudorhombila (Milne-Edwards). — M. Milne-Edwards states that the crustacean which is the type of this new genus is very remarkable, inasmuch as it holds a middle place between the Cancerians and the Gonoplaxes. The form of its carapace approaches that of the Panopes, and of some other Cancerians, for it is slightly arched in front, and between the orbits and the lateral borders a considerable portion of its contour is curved backwards after the manner of the latero-anterior border of the carapace of the Cyclometopes; but nevertheless its general form is that of a rhomb, and its posterior border occupies more than the third of its diameter. The body is very thick, and much elevated anteriorly. Front nearly horizontal, and divided into two truncated very large lobes. Eyes, antennæ, epistome, and external jaw-feet, presenting the same disposition as in the Crabs. Sternal plastron much wider than long, and very strongly curved from before backwards; at its posterior part, which is very wide, may be remarked on each side, in the male, a canal of considerable calibre, which lodges the intromissive organs, the origin of which may be seen at the base of the posterior feet. The anterior feet are very strong, and very long in the male; the succeeding feet present nothing remarkable, except that those of the form of the abdominal of the same length as those of the third pair, second pair are nearly rather shorter than the following ones. The and that these last are appendages differs but little from the form of those of *Xanthus*.

P. quadridentata. Length about 2 inches; colour rosy. Locality unknown.

M. Milne-Edward adds that the crustaceans figured by De Haan under the name of *Cancer* (*Curtonotus*) *longimanus* ('Fauna Japonica,' Crust., pl. vi. fig. 1) appear to him to come very near the preceding species; but as the description was not published, he could not pronounce upon their identity.

Gonoplax (Leach).—Carapace more than one and a half times as wide as it is long, and rather strongly narrowed backwards; the fronto-orbitary border extends the whole of its width, and the front itself is lamellar, slightly inclined, and terminated by a straight border. The ocular peduncles equal more than a third of the width of the carapace; they are of medium size, and present no notable swelling at their extremity. The internal antennæ are large and of ordinary form; the basilary joint of the external antennæ is small and cylindrical like the following ones, and their terminal stem is very long. The epistome is much less advanced than the lower border of the orbit; the buccal frame is much wider than it is long, and a little narrowed backwards; the form of the external jaw-feet is the same as in the crabs. The disposition of the sternal plastron is nearly the same as in *Pseudorhombila*, but it is to be remarked that the transversal canal which lodges each of the intromissive organs is not completely shut below. The anterior feet are extremely long and nearly cylindrical; those of the second pair are longer than the second or the third; and those of the last pair are nearly of the same length as the second. The abdomen of the male presents seven distinct joints, like that of the female.

G. rhomboides. M. Milne-Edwards remarks, that M. Latreille believed that this species could not be distinguished from *G. angulata*, and says that perhaps it may be only a variety; but he at the same time retains it as a species, and points out certain differences between it and *G. angulata*. Length about an inch; colour yellowish mingled with red.

Gonoplax rhomboides.

It inhabits the Mediterranean and the Ocean, and keeps among rocks at considerable depths, and seems to live solitary. According to M. Risso it swims with facility, and rises often to the surface of the water without ever coming out.

It feeds on small fish and radiated animals.

Professor Bell, in his 'British Crustacea,' says *G. angulata* is a British species, and states his conviction that *G. rhomboides* is only a variety.

Macrophthalmus (Latreille).—A genus with the general contour of *Gonoplax*, but distinguished by the form of the jaw-feet, and above all by the length of the ocular peduncles. Carapace rhomboidal and very wide; the transverse diameter is sometimes twice as long as the longitudinal diameter, and the anterior border occupies the whole length of it; stomachal region small and nearly quadrilateral; branchial regions large and nearly of the same form; front curved downwards, very narrow, and resembling that of *Ocypode;* it only occupies about the fifth of the transversal diameter of the carapace, and does not entirely cover the basilary portion of the ocular peduncles, which are very long, slender, and terminated by a somewhat oval and very small cornea. The orbits have the form of a transversal groove hollowed out under the anterior border of the carapace, and directed obliquely up; within, their inferior border is much more projecting than their superior border, but below the external angle it is incomplete, so that their cavity is not closed at this point. The internal antennæ are lodged under the front, and their stem, of a fair length, is bent transversely; the disposition of the external antennæ is nearly the same as in *Gonoplax*. The epistome is linear, and is continued with the lower orbitary border. The buccal frame is wider than it is long, and arched (cintré) in front. The external jaw-feet do not meet ('ne se rencontrent pas tout-à-fait'); their second joint is very wide, and the third much less, especially anteriorly, supports at the external angle of its anterior border the terminal stemlet ('tigelle terminale'). The sternal plastron is nearly of the same form as in *Gonoplax*, but much wider; and, in the male, instead of presenting transversal grooves for the lodgment of the intromissive organs, which in the genus last-named come out at the base of the posterior feet, it is itself perforated at a distance from the border to give a direct passage to these appendages of the spermatic conduits. The disposition of the feet is nearly the same as in *Gonoplax*.

M. transversus. Length about ten lines; some hairs on the feet.

It has been taken at Pondichéry. (Milne-Edwards.)

Cleistotoma (De Haan).—Front much wider than in *Macrophthalmus*, occupying about the third of the anterior border of the carapace, and a little inclined; ocular peduncles large, and of moderate length; orbits of the ordinary form; buccal frame at least as wide in front as behind; third joint of the external jaw-feet nearly of the same size as the second, and nearly square; anterior feet short in the two sexes.

C. Leachii. Carapace smooth and hairless; hands (manus) very large in the male; thighs granulous above. Length four lines.

It is found in the Red Sea.

M. Milne-Edwards thinks that *Ocypode* (*Cleistotoma*) *dilatata* (De Haan, 'Fauna Japonica,' Crust., pl. vii. fig. 3), the figure only of which is published, comes very near to *C. Leachii;* and he is also of opinion that the crustacean figured by M. Savigny, pl. ii. no. 2, and designated by M. Audouin as *Macrophthalmus Boscii* might be referred to this genus. M. Milne-Edwards however had not examined the buccal apparatus.

Fossil Gonoplacidæ.—M. Desmarest ('Hist. Nat. des Crustacés Fossiles') enumerates the following Fossil species of the genus *Gonoplax*, Leach:—*G. Latreillii*, generally incrusted in an argillaceous, grayish, rather hard limestone, which does not soften in water (calcaire argileux grisâtre assez dur, et qui ne se délaie pas dans l'eau); from the East Indies. *G. incisa* (*Cancer lapidescens* of Rumphius), incrusted in a gray, calcareous, argillaceous, and sandy stone; from the Indies, rather frequent. *G. emarginata* in an argillaceous, sandy, calcareous stone, of a yellowish-gray; frequent in collections, and noted as coming from the East Indies. *G. impressa*, approaching very near to the other species from the East Indies in its colour and in the incrusting stone, whence M. Desmarest is much inclined to think that it came from the same stratum. At the same time he says, that it should be stated that the specimen came to him from the Muséum d'Histoire Naturelle in a wrapper marked 'From Mount Marius, at Rome.' *G. incerta*, locality not mentioned; the specimen belonged to the Marquis de Drée.

M. Milne-Edwards observes, that the last-mentioned species, which is referred by M. Desmarest to the genus *Gonoplax*, approaches the recent species in form, and may well belong to the group; but its carapace is square instead of trapezoidal, and the lateral borders are not arched. M. Milne-Edwards is further of opinion that the greater part of the Fossil *Gonoplacidæ* described by M. Desmarest ought to be referred to the genus *Macrophthalmus* rather than to *Gonoplax*, for the form of their front, and even that of the carapace in general, is entirely that of the *Macrophthalmi*, and differs remarkably from the shape of the same parts in *Gonoplax;* and he records the following species:—*Macrophthalmus Latreillii* (*Gonoplax Latreillii*, Desm.); *M. incisus* (*Cancer lapidescens*, Rumph.; *G. incisa*, Desm.); *M. emarginatus*, Desm. Of *G. impressa* M. Milne-Edwards remarks that it comes very near the preceding species, but ought not to be referred to the same genus, because its carapace is nearly as long as it is wide, and its anterior feet are very short and convex (renflées).

GONOPLAX, a genus of Brachyurous Decapodous *Crustacea.* One of the species, *G. angulatus*, is found on the British coasts.

GONYOCEPHALUS. [DRACONINA.]

GOODENIACEÆ, *Goodeniads*, a small natural order of Exogenous Plants. The species are herbaceous plants, rarely shrubs, without milk, with simple or glandular hairs, if any are present; leaves scattered, often lobed, without stipules, very rarely opposite; inflorescence terminal, variable; flowers distinct, never capitate, usually yellow, blue, or pink. The calyx is usually superior, rarely inferior, equal or unequal in from three to five divisions. Corolla always more or less superior, monopetalous, more or less irregular, withering, its tube split at the back, and sometimes capable of being separated into five pieces. When the calyx only coheres with the base of the ovary, its limb 5-parted with one or two lips, the edges of the segments being thinner than the middle, and folded inwards in æstivation. Stamens 5, distinct, alternate with the segments of the corolla; anthers distinct or cohering, 2-celled, bursting longitudinally; pollen simple or in fours; ovary 1- or 2-celled, rarely 4-celled, with definite ovules. The fruit a 1-, 2-, or 4-celled capsule, with many solitary or numerous seeds attached to the axis of the dissepiment, which is usually parallel with the valves, rarely opposite to them. The great

2 1 3

Goodenia ovata.

1, a front view of a corolla; 2, the ovary with the stamens, style, and cupule surrounding the stigma; 3, the ovary with the superior calyx.

peculiarity of this order resides in the stigma, which is seated at the bottom of a cup or covering called an indusium; unknown in Bellworts or Lobeliads, to which the genera might otherwise be referred. It is of the same nature as what is found in Brunoniads and Styleworts, and is to be regarded as nothing more than a remarkable exaggeration of the rim which surrounds the stigmatic surface of Heathworts, and of the plates which cover the style of Cranesbills and Balsams. These plants belong to Australia and the islands of the Southern Ocean, or only advance into India in the form of a *Scævola.* There are 14 genera and 150 species. The order is allied to *Lobeliaceæ* and *Stylidiaceæ*.

GOODYERA, a genus of Plants belonging to the natural order *Orchidaceæ*, and the tribe *Limodoreæ.* It has a ringent perianth; the lips entire, included, saccate at the base; the stigma rostellated, subcordate; the rostellum erect, bipartite, with a large squarish appendage between its slender segments. One species of this genus, *G. repens*, is found in Scotland. It has a stem 6 to 8 inches high, with the radical leaves ovate, stalked, reticulated, and the whole upper part of the plant covered with minute stalked glands. It is found principally in fir-forests. (Babington, *Manual.*)

GOOSANDER. [DUCKS.]

GOOSE. [DUCKS.]

GOOSEBERRY. [RIBES.]

GOOSE-GRASS. [GALIUM.]

GORAL. [ANTILOPEÆ.]

GORE-BILL. [BELONE.]

GORGONIA, a genus of Animals belonging to the order *Polypifera*, and the type of the family *Gorgoniadæ.* It has the following generic characters:—Polype-mass rooted, arborescent, consisting of a central axis backed with a polypiferous crust; the axis horny, continuous, and flexible, branched in co-equality with the polype-mass; the crust when recent soft and fleshy, when dried porous and friable; the orifices of the polype-cells more or less protuberant. The species of *Gorgonia* thus defined are not numerous. Dr. Johnston enumerates four species as being found on the British coasts.

G. verrucosa, the Warted Sea-Fan, is somewhat fan-shaped, much and irregularly branched, the branches cylindrical, flexuous, backed when dry with a white warted crust; segments of the cells unequal.

obtuse. This polype is found abundantly on the whole of the south coast of England. It lives in deep water.

G. pinnata, branched and pinnated, the branches compressed; polype-cells in regular rows on each margin, mammillate, unarmed. This species was dredged by Professor E. Forbes and Mr. M'Andrew in the sound of Skye, where they found it attached to stones in 30 fathoms water.

G. placomus, irregularly branched, the branches disposed in a dichotomous order and a flattish form, cylindrical, warty; cells protuberant, conical, surrounded at top by little spines. This is the Warted Sea-Fan of Ellis, and is found on the Cornish coast, but is rare.

G. anceps, the Sea-Willow of Ellis. It is branched, sub-dichotomous; branches with the flesh flat on each side, with a row of little mouths along both the margins. This is a rare species. It was found originally by its describer Mr. Dale, near Margate. It is of a violet colour when fresh. It is a doubtful native of our seas.

G. flabellum has been found on British coasts, but it has been undoubtedly accidental.

(Johnston, *British Zoophytes.*)

GORLANDITE. [LEAD.]

GORSE. [ULEX.]

GOSHAWK. [FALCONIDÆ.]

GOSSY'PIUM, a genus of Plants belonging to the natural order *Malvaceæ*, common to both the Old and New World, and which, from the hair, or cotton, enveloping its seed being so admirably adapted for weaving into cloth, is, after those affording food, one of the most important groups of plants. There can be no doubt that it is indigenous in America, as, besides the distinctness in species, specimens of cotton still attached to the seeds, as well as cloth fabricated from the former, have been brought by Mr. Cumming from the Peruvian tombs. Some of the cloth, consisting of chequered squares of black and white, very nearly resembles some modern patterns. Humboldt has moreover stated that it formed the only clothing of the natives of Mexico, and is one of the plants they most anciently cultivated. With respect to the Old World, the almost universal use of cotton as clothing in the East is well known; and as the species, so far as ascertained by botanists, appear to be Indian and Chinese, the historical investigation is interesting as proving an early communication between the civilised nations of remote antiquity. Though Rossellini incorrectly states that cotton was employed as mummy-cloth, it must have been known to the ancient Egyptians, as he found some of the seed in one of the monuments of Thebes. In later times, we learn from Arrian that muslin was exported from India to the Arabian Gulf, and from that country cotton was no doubt first made known to the rest of the world.

The Sanscrit name of the Cotton-Plant is 'karpasi,' and the Hindoo 'kupas;' the cotton itself is in the latter language called 'rooi.' The former is interesting, as 'karpasus' occurs in the 'Periplus' of Arrian, and is rendered by Dr. Vincent 'fine muslin.' It is derived from the Sanscrit 'karpasi,' from which probably, as indicated by the editor of 'Harris's Dictionary,' the Hebrew word 'karpas,' employed in the book of Esther (chap. i. v. 6), is also derived; so likewise the Latin 'carbasus.' Dr. Royle, in his 'Essay on the Antiquity of Hindoo Medicine' (note, p. 145), infers, that as in the above passage of Esther, white, green, and blue hangings fastened to pillars of marble are described in the court of the garden of the king's palace; the practice appears similar to what is now adopted in India, where calico curtains, usually in red and white stripes, and stuffed with cotton (commonly called 'purdahs'), are employed everywhere in India, and at Delhi even in the king's hall of audience. This consists of colonnades of pillars supporting a light roof in the court before the private apartments of the palace. On the outer rows of pillars these purdahs are suspended; hence, the author infers, we may understand the use to which were applied the rows of pillars in front of the palace in the ruins of Persepolis.

Cotton was no doubt in later times cultivated and manufactured into cloth. Pliny (lib. xix. c. 1) states that Upper Egypt produces a small shrub which some call 'gossypion,' others 'xylon,' bearing fruit like a nut, from the interior of which a kind of wool is produced, from which very white and soft cloth is manufactured. Had it been common in Egypt in the time of Herodotus, it could not have escaped him; as he says specially of the Indians, that they possess a kind of plant which, instead of fruit, produces wool of a finer and better quality than that of sheep: of this the natives make their clothes. Nearchus describes the dress of the Indians as being made of flax from trees ('Library of Entertaining Knowledge,' Egypt. Antiq., ii. p. 125). Theophrastus (lib. iv. c. 9) clearly describes the cotton with leaves like the vine as being abundant in the Island of Tylos in the Persian Gulf. Heeren, in his work on the 'Commerce of the Ancients,' comes to the conclusion that these plantations of cotton in the Island of Tylos were the result of the commerce with India, the true country of the cotton. The inferences from these quotations of the original introduction of cotton from India into Egypt are in some measure confirmed by there being no species of *Gossypium* indigenous and peculiar to the latter country. In conclusion, it is necessary to refer to the facility with which cotton is distinguished from linen to controvert the assertion of Rossellini that it was always employed for mummy-cloth; as the result of numerous observations by Bauer, &c., with the most powerful microscopes of modern times, and every variety of mummy-cloth, has proved that it is invariably composed of linen, and not of cotton cloth. The one fibre is easily distinguished from the other; that of cotton having a flat tape or riband-like appearance, while the fibre of the linen has a round tubular and even-jointed structure. (Egypt. Antiq., 'Library of Entertaining Knowledge,' vol. ii. p. 182.)

The genus *Gossypium* is characterised by having a double calyx, of which the inner is cup-shaped, obtusely 5-toothed, the outer or involucre tripartite, with the leaflets united at the base, cordate, with the margins irregularly cut. Stigmas, 3-5. Capsules, 3- or 5-celled, many-seeded. Seeds clothed with wool-like hairs, or cotton.

The species of *Gossypium* occupy naturally a belt probably exceeding the torrid zone in breadth, but in a cultivated state we have cotton now extending on one hand to the south of Europe, and Lower Virginia and even Maryland in the United States of America; while on the other we have it as far south as the Cape of Good Hope, and in America to the southern parts of Brazil. Within these limits it may also be seen cultivated at considerable elevations. Baron Humboldt mentions having seen it even at 9000 feet of elevation in the Equinoctial Andes, and in Mexico at 5500 feet. Dr. Royle states that it is cultivated in small quantities at 4000 feet of elevation in 30° N. lat. in the Himalayas. The localities suited for the production of cotton depend as much upon the climate as the soil, and also upon the specific peculiarities of the different kinds of cotton plants. That the production of cotton is so much influenced by external circumstances is not more remarkable than in many other cultivated plants; indeed, we might expect it to be more so from the susceptibility of this hairy development to the influence of situation. Humboldt has remarked that *G. Barbadense*, *G. hirsutum*, and *G. religiosum* flourish in a climate where the mean annual temperature is from 82° to 68°; but that *G. herbaceum* is successfully cultivated where, the summer heat being 75° or 73°, that of winter is not less than 46° or 48°. The cultivation of this cotton however does not depend so much on winter cold as on sufficient length of suitable summer heat. The thermometer in Upper Virginia is sometimes as low as zero of Fahrenheit in winter, and yet cotton can be cultivated during the long summer.

It is remarkable that a genus so important for its product, and so long known, and with comparatively so small a number of species, should yet have these undetermined. The celebrated De Candolle states, that no genus more urgently requires the labours of a monograph from a careful botanist who could have the opportunity of seeing the species in a living state. The confusion has in a great measure proceeded from botanists absurdly neglecting the cultivated in their search for new species; and cultivators being incompetent or unwilling to distinguish varieties from species, frequently raising the former to the rank of the latter, because the produce, in which alone they are interested, happened to be more or less valuable. In the proceedings of the East Indian Committee there is an interesting letter from Mr. Spalding, where he informs us that the American cultivators confine their attention to such plants as are of annual growth. 1st. The Nankeen Cotton, introduced at an early period. This is abundant in produce; the seed covered with down, the wool of a dirty yellow colour, and usually low priced. 2nd. The Green-Seed Cotton with white wool, which, with the former, is grown in the middle and upland districts, whence the latter is called Upland Cotton, also Short Staple Cotton, and, from the mode in which it was cleaned, Bowed Georgia Cotton. 3rd. The Sea-Island or Long Staple Cotton, which is distinguished by the black colour of its seed, and by the fine, white, strong, and silky long staple by which it is surrounded. This is grown in the lower parts of Georgia and South Carolina, near the sea, and on several small islands which are not very distant from the shore.

The species admitted by botanists are not yet clearly determined. M. De Candolle admits 13 species, and notices others. Two have since been described by Dr. Roxburgh, one by Rœusch, and another in the 'Flore de Senegambie.' Of varieties Mr. Bennett says he knows more than one hundred kinds, and that they appeared to him never-ending. Dr. Royle, the most recent author who has treated expressly of the species, admits eight species, in which are absorbed some of De Candolle's; while others are avowedly unnoticed for want of materials for satisfactory determination. But from his own observations, Dr. Roxburgh's 'Flora Indica,' as well as from Swartz, 'Observ. Bot.' for the West Indies, and the specimens, though few, in the British Museum, it is probable that several of the cultivated species are correctly determined.

G. herbaceum (Linn.), which is herbaceous in temperate, and usually with bi-triennial stems 4-6 feet high in tropical countries, is no doubt the *Xylon* s. *G. antiquorum*, and includes also the *G. Indicum* of Lamarck, which would indeed be the preferrible name for this species. The younger parts of the stem, as well as the flower- and leaf-stalks, hairy and marked with black spots. Leaves hairy, palmate, 3- (generally) 5-lobed, lobes broad and rounded with a little point, or in the woody varieties sub-lanceolate and acute. Stipules falcate, lanceolate. Flowers of a lively yellow colour, with a purple spot near the claw. Segments of exterior calyx dentate, sometimes entire. Capsules ovate, pointed, 3- or 4-celled. Seeds free, clothed with finely-adhering grayish down under the short-staple white wool.

This and its varieties are those chiefly cultivated in India. It has been procured from China and the Malayan Peninsula, and also from Egypt. *G. punctatum*, from Senegambia, is probably a variety. It is that cultivated in the Mediterranean region, and must have been the species taken to America from Smyrna.

G. arboreum, Linn. Stem arboreous, 15-20 feet, sometimes shrubby, young parts hairy, tinged of a reddish colour. Leaves palmate, 3- or 4-lobed, hairy, dotted with blackish spots of a dark green colour; lobes elongated, lanceolate, sometimes mucronate, sinus obtuse, glands one, sometimes three. Stipules oval-shaped. Flowers solitary, with short peduncles, red, with a yellowish tinge near the claws. Leaflets of the exterior calyx cordate, ovate, entire, sometimes dentate. Capsule ovate-pointed, 3- or 4-celled, seeds covered with a greenish-coloured fur, enveloped in fine silky yellowish-white wool. This species is found in the island of Celebes and in every part of India. It is noticed among lists of the plants of Arabia, and also of Egypt. It is planted near temples and habitations of Faqueers in India, and is stated to be sacred to the Hindoo deities, and therefore employed only for making muslin for turbans. The species is marked *G. religiosum* in Heyne's 'Herbarium,' and one specimen of *G. Barbadense* is marked *G. arboreum* in the 'Linnean Herbarium.'

G. religiosum. Perennial. Stem 3-4 feet, branches and petioles a little velvety, hirsute towards the apex, and covered with black points. Leaves cordate, superior 3-lobed, inferior 5-lobed, deeply divided; lobes ovate-acuminate, entire, pubescent (some of the lower ones ovate-acuminate), one to three glands; stipules lanceolate, deciduous (cordate-acuminate, Roxb.). Flowers large, fulvous, peduncles short, dotted; leaflets of the exterior calyx large, cordate-acuminate, deeply laciniate, hairy and dotted; capsule ovate-acuminate, dotted, 3- 4- or 5-celled; seeds black, covered with firmly-adhering short tawny fur under the long tawny-coloured wool.

Gossypium Barbadense.

1, branch with full and half-blown flowers; 2, capsule burst open, showing the cotton in three divisions corresponding with the cells of the capsule; 3, a seed enveloped with cotton.

There is considerable confusion with respect to the species which should be called *G. religiosum*. The distinguishing characteristic of what is considered such at present is the having tawny-coloured instead of white wool. There are at least two distinct localities for this kind of cotton, one Siam, the other China. From the latter country it was introduced both into India and America under the name of Nankin Cotton. Dr. Royle is of opinion that two distinct species yield tawny-coloured cotton; one with small velvety-looking leaves and much dotted in every part, of which he has seen specimens from Macao, Tahiti, and Guzerat. The other is a much larger plant, with the general appearance and leaves of *G. Barbadense*, of which there are specimens in the 'East Indian Herbarium.' Mr. Wilkinson has brought specimens from Egypt of a rather tawny-coloured cotton, with brownish seed, free from fur, which he says is there called 'gotun Hindeo.'

G. hirsutum, Linn. Shrubby, about six feet high, young pods very hairy. Leaves, the upper undivided, cordate, acute; the lower 3- or 5-lobed; lobes ovate, acute (triangular, Roxb.), hairy on the under and smooth on the upper surface. Petioles very hairy, dotted with black spots; glands 1 or 2 to 3; stipules lanceolate (Cavanilles); corolla, base yellow, purplish towards apex (uniform yellow, Roxb.); exterior calyx ovate-acute, very hairy, cordate, 3-toothed (Cav. laciniate, Roxb.); capsule large, ovate-acute; seeds many, free, clothed with firmly-adhering green down under the fine long white wool. (Swartz.) This species is cultivated in Jamaica, according to Swartz; and would appear, from the description of the seed, to be the Green-Seeded, Short-Staple, or Upland Cotton of the Americans.

G. Barbadense. Stem shrubby, 6-15 feet, smooth; leaves, the upper 3-lobed, the lower 5-lobed; lobes ovate, acute, smooth, often pubescent on the under surface; leaflets of exterior calyx large, deeply laciniate; flowers yellow; capsule ovate, acuminate, smooth; seeds 8-12, free, oblong, black, and without any other pubescence than the long fine easily-separable cotton. Swartz describes this species as extensively cultivated in the West Indies: it is also the *G. vitifolium* of Cavanilles. It is one of the cultivated cottons of Egypt.

It is more than probable that the Sea-Island or Long Staple Cotton is a variety of this species, as its seeds agree in character. More than this it is not possible to say, as, among the numerous collections which London contains, strange to relate, there are none in which genuine specimens of cultivated cottons, properly named, can be seen; but it is to be hoped that travellers and naturalists will be induced to pay a little more attention to the products of a country, whether natural or the result of art, and deposit them in our museums, with the plants which produce them.

Several other species, as *G. punctatum*, from Senegal; *G. obtusifolium*, from Ceylon; and *G. Peruvianum*, from Brazil, have been described; but Dr. Royle is of opinion that all the species of cotton may be reduced to four—*G. Peruvianum* (*G. acuminatum*); *G. Indicum* (*G. herbaceum*); *G. arboreum*; and *G. Barbadense*.

For further information the reader is referred to the works quoted above, and to Royle's 'Illustrations of the Botany, &c., of the Himalayan Mountains.' [COTTON, in ARTS AND SC. DIV.]

GÖTHITE, a Mineral, to which also the name *Lepidokromite* is given. It is a hydrous peroxide of iron, differing from the brown iron-ore by containing half as much water. The crystals are of a brown colour, and blood-red by transmitted light when sub-transparent. It has a hardness of 5; and its specific gravity 4 to 4·2. It is found with hæmatite at Eiserfeld in Nassau, at Clifton in Cornwall, also in Siberia. *Turgite*, from the Ural, seems to be identical.

GOUR. [BOVIDÆ.]

GOURD, a kind of fruit obtained from various plants of the natural order *Cucurbitaceæ*. In countries having hot and dry summers the different kinds of this fruit are held in high estimation, and are a valuable article of consumption, acquiring a very large size, abounding in nutritious matter, and being moreover very wholesome. The largest is the kind called Potiron Jaune by the French, which sometimes weighs above 2 cwt. All the most esteemed kinds belong to the genus *Cucurbita*, the species of which are almost entirely destitute of the bitterness that renders other fruits of the same natural order unfit for food: thus the Vegetable Marrow is supplied by the *Cucurbita ovifera*; the Potiron by *C. maxima*; the Squash-Gourd, a very delicate sort, and perhaps the most agreeable of all when cooked in a very young state, by *C. melopepo*; and the Orange-Gourd by *C. aurantia*. Bottle-Gourds, which are bitter and dangerously drastic, are the fruit of *Lagenaria vulgaris*; while what is called the Colocynth-Gourd, a powerful purgative, is in reality a kind of melon, the *Cucumis colocynthis*. [CUCURBITACEÆ.]

GOWDIE, a name for the fish called the Sword Dragonet. [CALLIONYMUS.]

GOWDNOOK. [SCOMBERESOX.]

GRACILLARIA. [ALGÆ; RHODYMENIACEÆ.]

GRACULA. [CORACIAS.]

GRAINING. [LEUCISCUS.]

GRAINS OF PARADISE are hot, acrid, aromatic seeds, produced upon the coast of Guinea, and used for medicinal and other purposes as stomachic and cordial stimulants. They are produced by the *Amomum Grana Paradisi* of Linnæus, and *Amomum grandiflorum* of Smith. [AMOMUM.]

GRALLÆ (Wading-Birds), the fourth order of the class *Aves*, according to Linnæus, and placed by him, in his last edition of the 'Systema Naturæ,' between the orders *Anseres* (the third) and *Gallinæ* (the fifth).

Linnæus thus characterises the *Grallæ*:—Bill (a sounding staff, 'bacillus tentans') subcylindrical. Feet wading, the thighs half naked. Body compressed, the skin very thin, sapid; the tail short. Food, consisting of animalcules, obtained in marshes. Nest most frequently made on the ground; sexual congress varying ('nuptiis variis'). Analogous to the *Bruta*.

The same author divides the order into two sections:—

* Feet four-toed.

Phœnicopterus, Platalea, Palamedea, Mycteria, Tantalus, Ardea, Recurvirostra, Scolopax, Tringa, Fulica, Parra, Rallus, Psophia, Cancroma.

** Feet cursorial, that is, 3-toed.

Hæmatopus, Charadrius, Otis, Struthio.

In the body of the work Linnæus gives the following definition of the *Grallæ*:—Bill subcylindrical, rather obtuse. Tongue entire, fleshy. Thighs naked above the knees. [GRALLATORES.]

GRALLATORES (Illiger), the fourth order of Birds according to the system of Mr. Vigors, the *Rasores* being the third, and the *Natatores* the fifth.

Mr. Vigors considers the *Grallatores* as one of the aberrant groups of the class, and as exhibiting an equally circumscribed sphere of action as the *Rasores*. Holding an intermediate station between the Gallinaceous Birds, which are restricted to the land, and the Natatorial groups, which are confined to the water, their typical groups appear to Mr. Vigors to be those which partake most equally of the advantages of both elements; and the aberrant groups those which discover a more predominant inclination to either. "Of the five families," continues Mr. Vigors, "into which the order before us branches out, we may, in this point of view, pronounce those two to be most typical which inhabit the land, but derive their support from the water, or, to speak more correctly, which derive their whole support from the latter element, without possessing those powers of swimming or diving which are peculiar to the true water-fowl. The exclusive food of such groups will be fish, water reptiles and insects, *Mollusca*, and animalcules; and their distinguishing external characters, length of legs and bill, the former for the purpose of wading, the latter for that of seizing their prey, or of extracting it by suction from the waters or marshes. Of the three remaining families, two, as I have observed in an early part of this inquiry, will be found to deviate from the more typical, in their food and manners being more terrestrial, and their general appearance and structure more conformable to that of some groups of the preceding order of *Rasores*: while the third, by its capability of swimming and the rudiments of the natatorial membrane that connects the fore toes of some of its species, equally deserts the same type, and goes off, on the other hand, to the *Natatores*. Taking these peculiarities into consideration, we may venture to view the order according to the following arrangement, placing, as usual, the more typical families in the centre:—

Gruidæ.
Ardeidæ, Leach.
Scolopacidæ.
Rallidæ, Leach.
Charadriadæ, Leach.

"The following disposition distinguishes the normal and aberrant families:—

Normal Group.

Bills long, principally fitted for suction . . { *Ardeidæ.* *Scolopacidæ.*

Aberrant Group.

Bills short, and fitted for capturing, not sucking { *Rallidæ.* *Charadriadæ.* *Gruidæ.*"

The species that enter into the different families are noticed in the articles which treat of them, as well as the mode of union between one family and another.

Mr. W. S. M'Leay, in his paper 'On the Comparative Anatomy of Certain Birds of Cuba,' observes that the relations of analogy pointed out by Linnæus between *Mammalia* and Birds are, as Hermann has observed, not always correct; and that his errors have arisen from the misfortune of his not detecting the natural group of Aristotle and Ray, which the latter has called *Ungulata*. "Having," says Mr. M'Leay, "only been able to seize Aristotle's subdivisions of Τὰ μὲν οὐκ ἀμφοδόντα, he lost the parallelism of analogy, and fell, as I shall hereafter show, into very glaring mistakes. In the 'Systema Naturæ' however he has mentioned that very striking analogy which appears between the groups of *Grallæ* and *Bruta* [GRALLÆ], that is, according to the parallelism of analogy, between the order of *Grallatores* and *Ungulata*, since the *Bruta*, as we have seen, do not form an order, but only a natural subdivision of the *Ungulata*. That this analogy is demonstrably true, I deduce from the following facts. Of their respective classes, the orders of *Ungulata* and *Grallatores* contain examples of the longest legs in proportion to the body—witness *Camelopardalis* and *Hæmantopus* (*Himantopus* of authors?). Both orders present us, in groups not exactly aquatic, with instances of the toes being soldered together, as the Horse; or connected together with a web, as the Flamingo. Both orders present us with the greatest elongation of muzzle or facies—witness *Myrmecophaga* [ANT-EATER], or *Antilope* (particularly *A. Bubalus*) [ANTILOPEÆ], and *Scolopax*; and also with the most depressed form of muzzle—witness *Hippopotamus* and *Platalea*, which genera also afford us the truest specimens of wading *Vertebrata*. In both orders we have the most elongated claws—witness *Megalonyx* and *Parra*. Both orders afford us the swiftest animals in running—as the Horse and *Tachydromus*; and the most pugnacious on account of love—as the Bull and *Machetes*. The Bull moreover and the *Butor* (or *Bostaurus*, for hence comes the bird's name) [BITTERN], afford us the loudest and hoarsest voice of their respective orders; where we have also the most remarkable instances of the upper and under mandible touching each other merely at their base and point, as *Myrmecophaga*, or the whole of the Τὰ μὲν οὐκ ἀμφοδόντα of Aristotle, and *Anastomus*, Illig. Both orders exhibit ornamental appendages to the head—as the antlers of the Stag and the crown of the Crane; and both afford us the only instances of true horns, as *Bos*, or *Rhinoceros*, and *Palamedea*, Linn. To see a hundred such instances of resemblance it is only necessary to walk into a museum. I shall therefore only further say, that both orders contain polygamous animals, are generally gregarious, and more graminivorous than granivorous, being essentially inhabitants of marshes and savannahs. Thus then with Linnæus I place the *Bruta*, or rather the whole order of *Ungulata*, to which they belong, opposite to the *Grallatores*."

Mr. M'Leay then proceeds to observe that four orders in each class being disposed of, it follows by parallelism of analogy that the *Glires* ought to be placed opposite to the *Rasores*. But he asks, setting theory wholly aside, is this position true in fact? Linnæus, he remarks, from the above-mentioned error in his series of affinity considered the *Rasores* to be analogous to his group of *Pecora*. But this group, according to Aristotle and Ray, is only a subdivision of *Ungulata*, which have, Mr. M'Leay considers, been now proved to be analogous to the *Grallatores*. If therefore, he concludes, Linnæus be right in making his *Bruta* analogous to the order of Wading Birds, it follows that his *Pecora* must be so also.

In the same paper therefore Mr. M'Leay gives the following tables of analogies between the *Mammalia* and *Aves*:—

	Animals typically	
1. *Feræ*	carnivorous	1. *Raptores.*
2. *Primates*	omnivorous	2. *Insessores.*
3. *Glires*	frugivorous	3. *Rasores.*
4. *Ungulata* .	frequenting the vicinity of water .	4. *Grallatores.*
5. *Cetacea*	aquatic	5. *Natatores.*

Scansores.	Insessores.	Aves.
Psittacidæ representing the .	*Dentirostres*, and therefore the . . .	*Raptores.*
Rhamphastidæ joining the .	*Conirostres*, and forming part of the	*Insessores.*
Cuculidæ forming part of the	*Scansores*, and joining the	*Rasores.*
Certhiadæ joining the	*Tenuirostres*, and representing the .	*Grallatores.*
Picidæ representing the . . .	*Fissirostres*, and therefore the . . .	*Natatores.*

The latter table, Mr. M'Leay observes, will express several analogical relations of the utmost value, and the reader will find them fully explained in Mr. M'Leay's memoir. ('Linn. Trans.,' vol. xvi. p. 1.)

Mr. Swainson ('Classification of Birds,' vol. i.) remarks, that the grallatorial or tenuirostral type is shown in birds, as in quadrupeds, by a great slenderness and elongation of the jaws, muzzle, or bill—for all these, he states, are merely different terms to express nearly the same thing; "The notch in the bill, when it exists, is very slight, and the feathers of the front are considerably advanced upon the base of the upper mandible. The opening of the nostrils is very long, often tumid, but never round. Great swiftness either of foot or of wing is a constant indication of this type. Sometimes, as in the Snipes, both these characters are united; at other times, as we see in the Humming-Birds, this swiftness is confined only to flight; while in some few, as in the Flamingo, the wings are short, but the feet very long. The aperture or gape of the mouth is generally very small, as in all suctorial animals,—witness the whole of the typical *Grallatores*, or Waders, and their representatives the *Trochilidæ*. The smallest birds, no less than the smallest quadrupeds, are of this type, which is again represented by the little gliriform *Mammalia*."

Mr. Swainson gives, in the same volume, the following table of analogies:—

Primary Types.	Orders of Birds.	Typical Characters.	Orders of Quadrupeds.
1. Typical	*Insessores*	Organs of prehension and general structure highly developed.	*Quadrumana.*
2. Sub-typical	*Raptores*	Carnivorous; claws retractile.	*Feræ.*
3. Aquatic	*Natatores*	Live and feed in the water; feet very short or none.	*Cetacea.*
4. Suctorial	*Grallatores*	Jaws much prolonged; burrow for their food.	*Glires.*
5. Rasorial	*Rasores*	Head with crests of horn or feathers; habits domestic; feet long, formed for walking.	*Ungulata.*

Mr. Swainson considers that "these analogies are so perfect, and the series so completely in unison with those of all other animals," that he deems it unnecessary to go into any long details.

In further support of the relation between the *Grallatores* and *Glires* insisted on also in the 'Natural History and Classification of

Quadrupeds,' Mr. Swainson adverts to the elongation of the upper jaw or mandible of these animals, a peculiarity which is more conspicuous, he says, in them and their representatives than in any other groups. "If," continues Mr. Swainson, "we examine, for instance, the bill of the woodcock family, we find that its termination in regard to the contour gives an almost ludicrous resemblance to the muzzle of a rat, particularly if we fancy that both were of the same size. Now it is perfectly clear, that as these two animals when feeding generally insert their muzzle in the ground, so there can be no doubt that this particular formation is essential to that propensity. The only quadrupeds, again, which have the snout inclining upwards, are of the gliriform type; and the only birds in which the bill takes the same direction are typical of the *Grallatores*. The *Sorex*, *Dasypus*, &c., are all types of the gliriform quadrupeds, as those of *Trochilus*, *Avosetta*, *Tringa*, are of the grallatorial structure in birds: so that the resemblance of the snout of *Nasua* and *Avosetta* are as like as it is possible, considering that one is a quadruped and the other a bird. To the same type also belongs the *Echidna*, or Porcupine Ant-Eater, the American genus *Myrmecophaga*, and the Indian *Manis*: all these are pre-eminently characterised by that great prolongation of muzzle which constitutes, as before mentioned, one of the chief characters of the type we are now illustrating." We have given Mr. Swainson's own words, that the reader may have an opportunity of forming his own opinion as to the premises and conclusion; and we must further add, with reference to this volume, that Mr. Swainson considers that the typical structure of the wading foot "is found in the Sandpipers (*Tringa*), Tatlers (*Totanus*), and Snipes (*Scolopax*)."

In the second volume of 'The Classification of Birds,' we find that Mr. Swainson considers that the families under which the Waders are naturally arranged are these:—"1, the *Ardeadæ*, or Herons; 2, the *Charadriadæ*, or Plovers; 3, the *Tringidæ*, or Sandpipers; 4, the *Rallidæ*, or Rails; 5, the *Tantalidæ*, or Ibices (Ibises)." Mr. Swainson is of opinion that the 2nd and 3rd are the typical groups. In the same volume, farther on, we find the families of the *Grallatores* in the following order:—*Ardeadæ*, *Tantalidæ*, *Rallidæ*, *Scolopacidæ*, *Charadriadæ*, and at pages 28, 32, &c., will be found other analogical tables and explanations regarding the order.

Fossil Grallatores.

The fossil remains of the families of this order will be noticed under the articles which treat of them. But we may here state that the remains of Wading Birds occur in various strata. For instance, in the gypsum of the Paris Basin (Tertiary—Eocene period of Lyell) the bones of birds referrible to the genera *Scolopax*, *Tringa*, and *Ibis* have been found; and, in the fresh-water formation of Tilgate Forest (secondary series) Dr. Mantell found the remains of a Wader larger than a common Heron. But this bird must have been a pigmy when compared with those gigantic Waders (apparently) whose footsteps Professor Hitchcock records as being preserved in the new red-sandstone of the valley of the Connecticut. The professor refers these fossil footsteps to at least seven species of *Grallatores* with very long legs, and ranging from the size of a snipe to twice the dimensions of an ostrich.

These footmarks, which Professor Hitchcock names *Ornithichnites*, were found at various depths beneath the actual surface in quarries of laminated flagstones, at five places near the banks of the river, within a distance of 30 miles. The inclination of the sandstone is from 5° to 30°, and the tracks appear to have been made on it before the strata were so inclined. Seven of these tracks, which the professor figures, are considered by him to have been made by seven different species, if not genera. The footsteps appear in regular succession on the continuous track of an animal in the act of walking or running, with the right and left foot always in their proper places. There is occasionally a variation in the distance of the intervals between each footstep on the same track, but to no greater amount than the alteration of its pace by the bird would explain. Many tracks of different individuals and different species are often found crossing each other, and the footsteps are sometimes crowded together in the same manner that impressions of the feet of ducks and geese are left on the muddy shore of the stream or pond where they resort. The professor remarks, however, that none of the footsteps appear to be those of web-footed birds; they most resemble, he states, those of *Grallæ* (Waders), or birds whose habits resemble those of *Grallæ*. The impressions of three toes are usually distinct, except in a few instances; that of the hind toe is mostly wanting, as in the footsteps of modern *Grallæ*. But we must now draw the reader's attention to the most remarkable among these footmarks, hitherto found in one quarry only, at Mount Thorn near Northampton, where were discovered four nearly parallel tracks of a gigantic bird, whose foot measured 15 inches in length, exclusive of the largest claw, which was 2 inches in length. All the three toes were broad and thick. In one of the tracks a regular succession of six of these enormous footsteps appeared at a distance of 4 feet from each other; in others the distance varied from 4 to 6 feet, and it is supposed that the latter was the longest step of this bird-giant whilst it was running.

The footsteps next to be noticed are those of another enormous bird, whose toes were however more slender than those of the last (*Ornithichnites giganteus*), but measured from 15 to 16 inches in length, exclusive of a remarkable appendage extending backwards from the heel 8 or 9 inches, and apparently intended to sustain the animal when walking on a soft bottom. The impressions of this appendage bear a resemblance to those of wiry feathers or coarse bristles, which appear to have sunk into the mud and sand nearly an inch deep; but the toes had sunk much deeper, and the mud was raised into a ridge several inches high round their impressions, similar to the elevation round the track of an elephant in clay. Six feet sometimes seem to have made the length of this bird's stride. Other tracks indicate shorter steps; and the smallest impression tallies with a foot of only an inch long, with a step ranging from 3 to 5 inches. It is to be noted that in every track the length of the step increases with the size of the foot, and is much longer than the steps of any known existing species of birds. A greater length of leg is thence inferred than that of modern Wading Birds; and it is considered that the steps which are 4 feet asunder probably indicate a leg of 6 feet in length.

The margin of shallow water subject to changes of level, and in which sediments of sand and mud were alternately deposited, appears to have been the locality where these ancient birds congregated. The inferred length of limb would have been well adapted for wading in such a place.

The bones of fishes only (*Palæothrissum*) have yet been found in the rock that has transmitted to us these footsteps, "which are of the highest interest to the palæontologist, as they establish the new fact of the existence of birds at the early epoch of the new red-sandstone formation; and further show that some of the most ancient forms of this class attained a size far exceeding that of the largest among the feathered inhabitants of the present world, and were adapted for wading and running rather than for flight."

(*American Journal of Science and Arts*, vol. xxix.; Buckland, *Bridgewater Treatise.*)

GRAMINA'CEÆ, or GRASSES, are a very extensive and important natural order of Endogenous Plants, comprehending many of the most valuable pasture plants, all those which yield corn, such as wheat, barley, and maize, the sole source of colonial sugar in the sugar-cane, and the most fragrant of all plants in the form of Andropogons. Their structure is among the most simple of the perfect forms of vegetation; a stem clothed with alternate leaves whose stalks are universally thin, and constituting as many sheaths to guard the young and rapidly growing shoots, a few rudimentary leaves collected at the ends of the branches of inflorescence, and constituting flowers, a very small number of stamens, and a single seed inclosed in a thin pericarp, are all that nature provides to enable these plants to preserve their race and to distinguish their numerous kinds from one another. Yet, with such a simple apparatus, many thousand species are so precisely characterised that the natural order of Grasses is perhaps one of the easiest to study and arrange, provided the task be commenced upon right principles. The floral leaves, called glumes, paleæ, and scales, offer a prodigious number of different appearances, according to the manner in which they are combined or modified; and the inflorescence, the number of stamens, the texture of the parts, or the relation of the sexes to each other, afford additional means by which the distinctive characters are varied.

This is, no doubt, one of the wise provisions of Providence by which man is enabled to distinguish good from evil, the useful from the useless, the profitable from the unprofitable. For in no class of plants is it more necessary than in grasses to know how to choose between different species. For instance, most grasses are saccharine and nutritious to cattle, but the species of *Holcus*, *Bromus*, &c., are as frequently worthless. There is a great difference between the value of grasses for pasture; certain kinds suit the meadows, others marshes, others upland fields, and others bleak and sterile hills, where they furnish valuable food for sheep: these kinds will not grow indiscriminately, or are not equally suitable for different soils and situations, and it is therefore essential for the husbandman that he should be capable of discriminating between them. Some indicate the quality of soil: the species of *Dactylis*, *Holcus*, and *Bromus* are inhabitants of sterile land; the *Festucæ* and *Alopecuri* of better soil; while various *Poæ* and *Cynosurus* are found only in pasture-land of excellent quality. Most grasses are perfectly harmless, if not nutritious; yet the single species *Lolium temulentum* is a deleterious species in the midst of harmless *Lolia*; and *Bromus purgans* and *Festuca quadridentata* afford similar instances of this singular exception to ordinary rules.

For these and similar reasons, classification, which at all times is so necessary, here becomes the very foundation of all correct knowledge, and it has accordingly very particularly excited the attention of systematic botanists from the time when the general term *Gramen* was broken up by Linnæus into a number of different genera. It is not desirable in this place to show by what degrees the knowledge of botanists upon this subject has advanced from the days of Linnæus up to the present time. Those who are desirous of gaining this information should consult Palisot de Beauvois' 'Agrostographie,' published at Paris in 1812, and the subsequent writings of Brown, Kunth, Nees von Esenbeck, and Trinius. We shall confine ourselves to a general technical description of the order, partly founded upon the 'Agrostographia synoptica' of Kunth, and to brief characters of its tribes as they stand in the 'Genera Plantarum' of Endlicher.

General Character.—Roots in all cases fibrous; stem, called culm by some authors, cylindrical, rarely compressed, varying in length from a few inches, as in *Knappia agrostidea*, to 80 or 90 feet, as in the Bamboo; usually fistular, except at the joints, where it is always solid; sometimes solid throughout, as in the Sugar-Cane; coated with silex, which is also secreted occasionally in lumps in the hollows of the stem under the form of the opalescent substance called 'tabasheer;' in most cases only of annual duration, but sometimes shrubby or arborescent. Leaves one to each node, with a sheathing petiole, the limb membranous, usually narrow; the sheath quite surrounding the stem, slit on one side, usually with a ligula at the apex. Spikelets terminal, panicled, racemose, or spiked; sometimes immersed in the thickened rachis; very seldom several fascicled, or united together, and surrounded by a general spathe. Flowers hermaphrodite, or polygamous, sometimes monœcious, very rarely diœcious, destitute of true calyx or corolla, surrounded by a double set of bracts, the outer constituting the glumes (or calyx of some authors), the inner the paleæ (or corolla of others); all together forming a distichous spikelet of one or more florets. Glumes alternate, the outer usually the largest and most distinctly ribbed, and often having its midrib extended into a beard or awn; sometimes both awned; sometimes the lower glume only present; occasionally both absent; these glumes are only found at the base of the spikelets, and may belong to one floret only or to many. Paleæ usually in pairs, and alternate with each other; the lower and outer 1-3-many-veined, usually keeled, awned or awnless; the upper and inner usually two-veined, more membranous, smaller, awnless, sometimes absent. Hypogynous scales regarded by Kunth as remains of the ligula; by most other botanists as the rudiments of a corolla, usually two on each side of the base of the inner palea; sometimes a third is added in front of the inner palea; sometimes united with each other, sometimes deficient. Stamens hypogynous, usually definite, very rarely indefinite; if six or three, placed all round the ovary; if fewer than three, placed next the outer palea; filaments long and flaccid; anthers versatile, linear, bifid at each end. Ovary solitary, simple, with two styles (rarely three), each having a feathered or branched stigma, one-celled, with a single ovule attached to the pericarp by the whole side, or the lower part of the side next the upper palea. Fruit a caryopsis in most cases, occasionally an utriculus; the pericarp thin and membranous, in the former case adhering firmly to the seeds, in the latter distinct from it. Seed containing a large quantity of floury albumen, on one side of which (that next the lower palea) there lies a lenticular embryo, composed of a thin cotyledon, whose edges are doubled outwards over the plumula and radicle, which therefore press upon the side of the pericarp next the outer palea. The plumula is free, and consists of several sheaths overlying each other; the radicle is composed of several tubercles which break through the sides of the embryo as soon as germination commences.

Under this character M. Kunth assembles about 2500 species, a number far below the real amount, which is probably near 4000, and M. Endlicher 234 genera (now increased to 291), which are classified by the latter botanist as follows:—

Tribe I. *Oryzeæ.*—Spikelets sometimes 1-flowered, with the glumes frequently absent; sometimes 2-3-flowered, with the lower florets consisting of but one palea, and neuter, the upper only being fertile. Paleæ of a stiff papery texture. Flowers often unisexual, usually hexandrous. This tribe includes the following genera:—

Leersia.	*Blepharochloa.*
Potamochloa.	*Oryza.*
Potamophila.	*Hydrochloa.*
Zizania.	*Hygroryza.*
Caryochloa.	*Luziola.*
Ehrharta.	*Tetrarrhena.*
Microlæna.	*Diplax.*
Pharus.	*Leptaspis.*

Oryza.

Tribe II. *Phalarideæ.*—Spikelets hermaphrodite, polygamous, or rarely monœcious; either 1-flowered, with or without a stipitiform rudiment of an upper floret; or 2-flowered, with both florets either hermaphrodite or male; or 2-3-flowered, with the terminal floret fertile, the rest incomplete. Glumes usually equal. Paleæ often shining, hardened in the fruit. Styles or stigmas mostly long. It includes the following genera:—

Lygeum.	*Zea.*
Coix.	*Chionanche.*
Sclerachne.	*Polytoca.*
Cornucopiæ.	*Crypsis.*
Mibora.	*Alopecurus.*
Limnas.	*Beckmannia.*
Phleum.	*Fingerhuthia.*
Chondrolæna.	*Hilaria.*
Phalaris.	*Digraphis.*
Holcus.	*Reynaudia.*
Desprezia.	

Phleum.

Tribe III. *Paniceæ.*—Spikelets 2-flowered, the lower floret being incomplete. Glumes thinner than the paleæ, the lowermost often, occasionally both, being abortive. Paleæ more or less coriaceous or papery, usually awnless, the lower concave. Caryopsis compressed from the back. It includes—

Reimaria.	*Paspalum.*
Milium.	*Amphicarpum.*
Olyra.	*Strephium.*
Thrasya.	*Eriochloa.*
Urochloa.	*Rhynchelytrum.*
Panicum.	*Ichnanthus.*
Bluffia.	*Isachne.*
Stenotaphrum.	*Acratherum.*
Berghausia.	*Melinis.*
Thysanolæna.	*Chætium.*
Oplismenus.	*Berchtoldia.*
Chamærhaphis.	*Pennisetum.*
Setaria.	*Gymnothrix.*
Penicillaria.	*Cenchrus.*
Trachyozus.	*Anthephora.*
Lappago.	*Lopholepis.*
Latipes.	*Echinolæna.*
Navicularia.	*Thouarea.*
Spinifex.	*Neurachne.*

Streptostachys.

Tribe IV. *Stipeæ.*—Spikelets 1-flowered. Lower paleæ rolled inwards, awned at the apex, and usually indurated in the fruit; awn simple or trifid, usually twisted, and articulated at the base. Ovary stipitate. Squamulæ usually three. Under this tribe are included—

Oryzopsis.	*Greenia.*
Piptatherum.	*Lasiagrostis.*
Dichelachne.	*Orthoraphium.*
Macrochloa.	*Stipa.*
Eriocoma.	*Streptachne.*
Aristida.	*Stipagrostis.*

Tribe V. *Agrostideæ.*—Spikelets 1-flowered, very rarely with the awl-shaped rudiment of an upper flower. Glumes and paleæ 2, membranous-herbaceous; the upper palea usually artistate. Stigmas usually sessile. This tribe includes—

Mühlenbergia. *Lycurus.* *Phippsia.* *Cinna.* *Echinopogon.* *Agrostis.* *Nowodworskya.* *Chæturus.* *Pereilema.* *Clomena.* *Coleanthus.* *Colpodium.* *Epicampes.* *Sporobolus.* *Gastridium.* *Polypogon.* *Ægopogon.*

Stipa.

Apera.

Tribe VI. *Arundineæ.*—Spikelets either 1-flowered, with or without the rudiment of an upper floret, or many-flowered. Florets usually surrounded or covered with long soft hairs. Glumes and paleæ 2, membranous-herbaceous, the former usually as long as the florets or longer, of the latter the lower awned or awnless. Usually tall grasses. It includes—

Sericura. *Deyeuxia.* *Pentapogon.* *Arundo.* *Graphephorum.* *Amphidonax.* *Calamagrostis.* *Lachnagrostis.* *Ammophila.* *Ampelodesmos.* *Phragmites.* *Gynerium.*

Calamagrostis.

Tribe VII. *Pappophoreæ.*—Spikelets 2-many-flowered, the upper withering. Glumes and paleæ 2, membranous-herbaceous. Lower palea with 3 or more subulate awned divisions. Inflorescence capitate-spiked or panicled. It includes—

Amphipogon. *Trirhaphis.* *Enneapogon.* *Euraphis.* *Echinaria.* *Diplopogon.* *Pappophorum.* *Polyrhaphis.* *Cottæa.* *Cathestecum.*

Enneapogon.

Tribe VIII. *Chlorideæ.*—Spikelets in unilateral spikes, 1-many-flowered; the upper florets withering. Glumes and paleæ 2, membranous-herbaceous, the latter awnless or awned, the former permanent on the rachis, and the anterior one inserted higher up than the other. Spikes digitate or panicled, rarely solitary. Rachis continuous, not jointed. It includes—

Microchloa. *Cynodon.* *Eustachys.* *Leptochloa.* *Harpochloa.* *Melanocenchris.* *Opizia.* *Eutriana.* *Aristidium.* *Triplathera.* *Gymnopogon.* *Pentarhaphis.* *Triæna.* *Pleuraphis.* *Schœnefeldia.* *Dactyloctenium.* *Chloris.* *Eleusine.* *Ctenium.* *Chondrosium.* *Spartina.* *Atheropogon.* *Heterostega.* *Triathera.* *Polyodon.* *Polyschistis.* *Triplasis.* *Bromidium.*

Chloris.

Tribe IX. *Aveneæ.*—Spikelets 2-many-flowered; the terminal floret usually withering. Glumes and paleæ 2, membranous-herbaceous; the lower palea mostly awned; the awn usually dorsal and twisted. It includes—

Hierochloe. *Ataxia.* *Corynephorus.* *Dupontia.* *Airopsis.* *Lagurus.* *Colobanthus.* *Trichæta.* *Avena.* *Tristachya.* *Trichopterya.* *Brandtia.* *Chætobromus.* *Triodia.* *Anthoxanthum.* *Podopogon.* *Deschampsia.* *Aira.* *Trisetaria.* *Trisetum.* *Rostraria.* *Acrospelion.* *Arrhenatherum.* *Anisopogon.* *Eriachne.* *Danthonia.* *Uralepis.* *Pommereulla.*

Danthonia.

Tribe X. *Festuceæ.*—Spikelets many-flowered, rarely few-flowered. Glumes and paleæ 2, membranous-herbaceous, rarely coriaceous, the latter usually furnished with an awn which is not twisted. Inflorescence almost always panicled. It includes—

Bromidæ.

Sesleria. *Æluropus.* *Dissanthelium.* *Phalaridium.* *Glyceria.* *Lophochlæna.* *Eatonia.* *Cœlachne.* *Chascolytrum.* *Poa.* *Eragrostis.* *Tetrachne.* *Centotheca.* *Hydrochloa.* *Pleuropogon.* *Catabrosa.* *Briza.* *Calotheca.*

Anthochloa.	*Melica.*
Molinia.	*Airochloa.*
Kœleria.	*Schismus.*
Wangenheimia.	*Dactylis.*
Lasiochloa.	*Urochlœna.*
Cynosurus.	*Chrysurus.*
Lamarckia.	*Ectrosia.*
Lophatherum.	*Elytrophorus.*
Plagiœlytrum.	*Festuca.*
Amphibromus.	*Bromus.*
Orthoclada.	*Uniola.*
Diarrhena.	

Bambusidæ.

Arundinaria.	*Arthrostylidium.*
Phyllostachys.	*Streptogyna.*
Chusquea.	*Merostachys.*
Guadua.	*Nastus.*
Schizostachyum.	*Bambusa.*
Beesha.	*Streptochæta.*

Briza.

Tribe XI. *Hordeæ.*—Spikelets 3-many-flowered; sometimes 1-flowered. Terminal floret withering. Glumes (occasionally deficient) and paleæ 2, herbaceous. Stigma sessile. Ovary mostly hairy. Inflorescence spiked; spike simple, solitary; rachis sometimes winged. In this tribe are collected the *Cerealia*, namely, wheat, barley, rye, &c. It includes—

Lolium.	*Triticum.*
Secale.	*Elymus.*
Gymnostichum.	*Hordeum.*
Ægilops.	*Polyanther ix.*
Pariana.	

Hordeum.

Tribe XII. *Rottboëllcæ.*—Inflorescence spiked; the rachis in most cases jointed. Spikelets 1-2- or very rarely 3 flowered, lodged in hollows of the rachis; either solitary or in pairs, one being stalked and withering. One floret of each spikelet, either the upper or the lower, usually incomplete. Glumes 1-2, sometimes altogether wanting,

Rottboëlla.

mostly coriaceous. Paleæ membranous, awnless, or now and then awned. Style 1-2, sometimes very short, or altogether absent. It includes—

Nardus.	*Psilurus.*
Lepturus.	*Oropetium.*
Ophiurus.	*Hemarthria.*
Vossia.	*Mnesithea.*
Rottboëlla.	*Ratzeburgia.*
Xerochloa.	*Tripsacum.*
Manisuris.	

Tribe XIII. *Andropogoneæ.*—Spikelets 2-flowered; the lower floret being almost always incomplete. Palea thinner than the glumes, usually transparent. It includes—

Perotis.	*Leptothrium.*
Zoysia.	*Dimeria.*
Arthraxon.	*Eriochrysis.*
Saccharum.	*Imperata.*
Pogonatherum.	*Erianthus.*
Eulalia.	*Leptatherum.*
Apocopis.	*Elionurus.*
Anthistiria.	*Perobachne.*
Diectomis.	*Apluda.*
Batratherum.	*Hologamium.*
Lepeocercis.	*Anatherum.*
Trachypogon.	*Andropogon.*
Heteropogon.	*Ischæmum.*
Pogonopsis.	*Thelepogon.*
Arthropogon.	*Zeugites.*
Alloteropsis.	*Blyttia.*

Pogonatherum.

The following list of British genera is from Babington's 'Manua of British Botany:'—

Digitaria.	*Echinochloa.*
Setaria.	*Phalaris.*
Anthoxanthum.	*Hierochloe.*
Phleum.	*Alopecurus.*
Knappia.	*Gastridium.*
Polypogon.	*Milium.*
Agrostis.	*Apera.*
Stipa.	*Arundo.*
Psamma.	*Phragmites.*
Cynodon.	*Spartina.*
Leersia.	*Sesleria.*
Lagurus.	*Aira.*
Corynephorus	*Trisetum.*
Avena.	*Arrhenatherum.*
Holcus.	*Triodia.*
Kœleria.	*Melica.*
Molinia.	*Catabrosa.*
Poa.	*Glyceria.*
Sclerochloa.	*Briza.*
Cynosurus.	*Dactylis.*
Festuca.	*Bromus.*
Serrafalcus.	*Brachypodium.*
Triticum.	*Lolium.*
Elymus.	*Hordeum.*
Nardus.	*Lepturus.*

"The family is very numerous. Persoon's 'Synopsis' contains 812 species, 1-26th part of all the plants therein enumerated. In the system of Roemer and Schultes there are 1800, and since this work, were it brought to a conclusion, would probably contain 40,000 in all, it may be assumed that the grasses form a 22nd part. It is more than probable however that in future the grasses will increase in a larger ratio than the other phanerogamic plants, and that perhaps the just proportion will be as 1 to 20 or as 1 to 16. Greater still will be their proportion to vegetation in general when the number of individuals is taken into account, for in this respect the greater number, nay perhaps the whole, of the other classes are inferior. With regard to locality in such a large family, very little can be advanced.

"Among the grasses there are both land and water, but no marine plants. They occur in every soil, in society of others and alone, the last in such a degree as entirely to occupy considerable districts. Sand appears to be less favourable to this class, but even this has species nearly peculiar to itself. The diffusion of this family has almost no other limits than those of the whole vegetable kingdom. Grasses occur under the equator, and *Agrostis algida* was one of the few plants which Phipps met with on Spitzbergen. On the mountains of the south of Europe *Poa disticha* and other grasses ascend almost to the snow line, and on the Andes this is also the case with *P. malulensis* and *P. dactyloides*, *Deyeuxia rigida*, and *Festuca dasyantha*. The greatest differences between tropical and extra-tropical grasses appear to be the following:—

"1. The tropical grasses acquire a much greater height, and occasionally assume the appearance of trees. Some species of *Bambusa* are from 50 to 60 feet high.

"2. The leaves of the tropical grasses are broader and approach more in form to those of other families of plants. Of this the genus *Paspalus* affords many examples.

"3. Separate sexes are more frequent in the tropical grasses. *Zea*, *Sorghum*, *Andropogon*, *Olyra*, *Anthistiria*, *Ischæmum*, *Ægilops*, and many other genera which only occur in the torrid zone, and are there found in perfection, are monœcious or polygamous. *Holcus* is perhaps the only extra-tropical genus with separate sexes.

"4. The flowers are softer, more downy, and elegant.

"5. The extra-tropical grasses on the contrary far surpass the tropical in respect of the number of individuals.

"That compact grassy turf, which especially in the colder parts of the temperate zones in spring and summer composes the green meadows and pastures, is almost entirely wanting in the torrid zone. The grasses there do not grow crowded together, but like other plants, more dispersed. Even in the southern parts of Europe the assimilation to the warmer regions in this respect is by no means inconsiderable.

"*Arundo donax* by its height reminds us of the Bamboo, *Saccharum Ravennæ*, *S. Teneriffæ*, *Imperata arundinacea*, *Lagurus ovatus*, *Lygeum spartum*, and the species of *Andropogon*, *Ægilops*, &c., by separate sexes exhibit tropical qualities. The grasses are also less gregarious, and meadows seldomer occur in the south than in the north of Europe. The generality are social plants.

"The distribution of cultivated grasses is one of the most interesting of all subjects. It is determined not merely by climate but depends on the civilisation, industry, and traffic of the people, and often on historical events. Within the northern polar circle agriculture is found only in a few places. In Siberia grain reaches at the utmost only to 60°, in the eastern parts scarcely above 55°, and in Kamtschatka there is no agriculture even in the most southern parts (51°). The polar limit of agriculture on the north-west coast of America appears to be somewhat higher, for in the more southern Russian possessions (57° to 52°) barley and rye come to maturity. Only in Europe, namely in Lapland, does the polar limit reach an unusually high latitude. Beyond this dried fish, and here and there potatoes, supply the place of grain.

"The grains which extend farthest to the north in Europe are barley and oats. These, which in the milder climates are not used for bread, afford to the inhabitants of the northern parts of Norway and Sweden, of a part of Siberia and Scotland, their chief vegetable nourishment. Rye is the next which becomes associated with these. This is the prevailing grain in a great part of the northern temperate zone, namely in the south of Sweden and Norway, Denmark, and in all the lands bordering on the Baltic, the north of Germany, and part of Siberia. In the latter another very nutritious grain, buckwheat, is very frequently cultivated. In the zone where rye prevails wheat is generally to be found, barely being here chiefly cultivated for the manufacture of beer, and oats supplying food for the horses. To these there follows a zone in Europe and Western Asia where rye disappears, and wheat almost exclusively furnishes bread. The middle and the south of France, England, part of Scotland, a part of Germany, Hungary, the Crimea, and Caucasus, as also the lands of middle Asia, where agriculture is followed, belong to this zone. Here the vine is also found, wine supplants the use of beer, and barley is consequently less raised. Next comes a district where wheat still abounds, but no longer exclusively furnishes bread, rice and maize becoming frequent. To this zone belong Portugal, Spain, part of France on the Mediterranean, Italy and Greece, further, the countries of the East, Persia, Northern India, Arabia, Egypt, Nubia, Barbary, and the Canary Islands; in these latter countries however the culture of maize or rice towards the south is always more considerable, and in some of them several kinds of *Sorghum* (Doura) and *Poa Abyssinica* come to be added. In both these regions of wheat, rye only occurs at a considerable elevation, oats however more seldom, and at last entirely disappear, barley affording food for horses and mules. In the eastern parts of the temperate zone of the old continent, in China and Japan, our northern kinds of grain are very unfrequent, and rice is found to predominate. The cause of this difference between the east and the west of the old continent appears to be in the manners and peculiarities of the people. In North America, wheat and rye grow as in Europe, but more sparingly. Maize is more reared in the western than in the old continent, and rice predominates in the southern provinces of the United States. In the torrid zone, maize predominates in America, rice in Asia; and both these grains in nearly equal quantity in Africa.

"The cause of this distribution is, without doubt, historical, for Asia is the native country of rice, and America of maize. In some situations, especially in the neighbourhood of the tropics, wheat is also met with, but always subordinate to these other kinds of grain. Besides rice and maize there are in the torrid zone several kinds of grain as well as other plants which supply the inhabitants with food, either used along with them or entirely occupying their place. Such are, in the new continent, Yams (*Dioscorea alata*), the Manihot (*Jatropha Manihot*), and the Batatas (*Convolvulus Batatas*), the root of which and the fruit of the Pisang (*Banana Musa*) furnish universal articles of food; in the same zone in Africa, Doura (*Sorghum*), Pisang, Manihot, Yams, and *Arachis hypogæa*; in the East Indies and on the Indian Islands, *Eleusine coracana*, *E. stricta*, *Panicum frumentaceum*, several Palms, and *Cycadaceæ* which produce the Sago, Pisang, Yams, Batatas, and the Broad-Fruit (*Artocarpus incisa*). In the islands of the South Sea, grain of every kind disappears, its place being supplied by the bread-fruit tree, the pisang, and *Tacca pinnatifida*. In the tropical parts of Australia there is no agriculture, the inhabitants living on the produce of the sago, of various palms, and some species of *Arum*.

"In the high lands of South America, there is a distribution similar to that of the degrees of latitude. Maize indeed grows to the height of 7200 feet above the level of the sea, but only predominates between 3000 and 6000 feet of elevation. Below 3000 feet it is associated with the pisang and the above mentioned vegetables, while from 6000 to 9260 feet the European grains abound: wheat in the lower regions, rye and barley in the higher, along with which *Chenopodium Quinoa* as a nutritious plant must also be enumerated. Potatoes alone are cultivated from 9260 to 12,300 feet. To the south of the tropic of Capricorn, wherever agriculture is practised, considerable resemblance with the northern temperate zone may be observed. In the southern parts of Brazil, in Buenos Ayres, in Chili, at the Cape of Good Hope, and in the temperate zone of Australia, wheat predominates; barley however and rye make their appearance in the southernmost parts of these countries, and in Van Diemen's Land. In New Zealand the culture of wheat is said to have been tried with success, but the inhabitants avail themselves of the *Acrostichum furcatum* as the main article of sustenance. Hence it appears that in respect of the predominating kinds of grain, the earth may be divided into five grand divisions, or kingdoms — the kingdom of rice, of maize, of wheat, of rye, and lastly of barley and oats. The first three are the most extensive; the maize has the greatest range of temperature, but rice may be said to support the greatest number of the human race." Schouw, in Jameson's 'Philosophical Journal.'

The uses of this most important tribe of plants for fodder, food, and clothing, require little illustration. The abundance of wholesome fæcula contained in their seeds renders them peculiarly well adapted for the sustenance of man; and if the Cereal Grasses only, such as Wheat, Barley, Rye, Oats, Maize, Rice, and Guinea Corn, are the kinds commonly employed, it is because of the large size of their grain compared with that of other grasses; for none are unwholesome in their natural state with the exception of *Lolium temulentum*, a common weed in many parts of England, the effects of which are undoubtedly injurious. *Bromus purgans* and *catharticus* are said to be emetic and purgative; *Bromus mollis* is also unwholesome, and *Festuca quadridentata* is said to be poisonous; *Molinia varia* is injurious to cattle; and some other species are supposed to affect the milk of cows which graze upon them.

Among corn-plants not generally known may be mentioned *Eleusine caracana*, called Natchuco on the Coromandel coast, and Nagla Ragee, or Mand, elsewhere in India; *Setaria Germanica*, yielding German millet; and *Panicum frumentaceum*. There are many other species.

The value of grasses as fodder for cattle is hardly less than that of corn for human food. The best fodder-grasses of Europe are usually dwarf species, or at least such as do not rise above four or five feet from the ground. The most esteemed are *Lolium perenne*, *Phleum*, and *Festuca pratensis*; *Cynosurus cristatus*, and various species of *Poa* and dwarf *Festuca*. The fodder-grasses of Brazil are of far more gigantic stature, and perfectly tender and delicate. In Australia the favourite is *Anthistiria australis*, or Kangaroo Grass; in India *A. ciliata* is also in request; but the most common Indian fodder-grass is Doorba, Doorwa, or Hurryaleo (*Cynodon dactylon*). Gama Grass (*Tripsacum dactyloides*) has a great reputation as fodder in Mexico; and attention has lately been directed to the Tussac Grass of the Falklands (*Festuca flabellata*), a species forming tufts five or six feet high, and said to be unrivalled for its excellence as food for cattle and horses.

The fragrance of our sweet Vernal Grass is by no means confined to it; other species possess the same quality, which is connected with the presence of aromatic secretions, which have in part recommended grasses to the notice of medical practitioners. Sugar is a general product of grasses. It exists in great quantities in the Sugar-Cane (*Saccharum officinarum*). Maize so abounds in it, that its cultivation has been proposed in lieu of the sugar-cane.

For economical purposes Grasses are often of much importance. The strong stems of the bamboo are employed instead of timber and cordage. The cuticle of some species contains silex, which occurs in large masses after the burning of a heap of corn or a stack of hay in the shape of a colourless glass mass.

For an account of the diseases of this tribe of plants see ENTOPHYTA, ERGOT, and FUNGI. The uses of various species are described under ANATHERUM, COIX, DONAX, ELEUSINE, CYNODON, GYNERIUM, ARUNDO, and ELYMUS.

GRAMMATITE. [HORNBLENDE.]

GRAMMATOPHORA. [DRACONINA.]

GRAMPUS. [CETACEA.]

GRANADILLA. [PASSIFLORA.]

GRANATEÆ, a natural order of Plants separated by David Don from *Myrtaceæ* [MYRTACEÆ], and containing only the species of the genus *Punica*. [PUNICA.] It differs from *Myrtaceæ* in the leaves being destitute of glands, and in being without the intramarginal vein, as also in the nature of its fruit, its pulpy seeds, and convolute cotyledons. (G. Don, *Dichlamydeous Plants.*)

GRANATUM. [PUNICA.]

GRANITE, one of the most abundant rocks seen at or near the surface of the earth, and, from the variety of discussions to which it has given rise, one of the most celebrated. Wherever the stratified rocks, which were deposited by water, are seen to their very base, they are in all quarters of the world observed to rest on other unstratified rocks of the nature of granite. This rock appears in many instances to have been in a fluid state since the deposition of those strata which cover it, for it is seen to penetrate into their cracks and fissures, just as iron enters in veins the cracks of the sandstone which forms the sides or bed of the furnace. The fluidity of granitic rocks is now almost universally attributed, and with sufficient reason, to the effect of great heat analogous in its origin to that which supplies the energies of volcanoes, but probably more general in its distribution and more uniform in its action.

It is impossible to say how much of the mass of the earth is composed of granitic rocks, though from the matter thrown up by volcanoes we see that mineral compounds in some degree analogous exist to considerable depths. To what extent it can be demonstrated that the sedimentary stratified rocks have been derived from disintegrated granites is yet uncertain, and Sir Charles Lyell has recently introduced the consideration of the more difficult question, whether granite has not been produced and may not still be forming by the remelting of such sedimentary aggregates into the general mass of the interior of the globe. The bare mention of such expanded views shows the high interest which attaches to the contemplation of granite. [GEOLOGY.]

Granite is one of the most beautiful of rocks, and viewed mineralogically its composition is remarkable. Mica, felspar, and quartz, in distinct crystals, or else filling interstices between crystals, constitute the typical varieties, and the most abundant masses of granite; but it is impossible so to limit the signification of the term. Hornblende must be included among the legitimate constituents of granite, if we are to use the term in a manner at all consistent with geological experience or the variations of granitic compounds. Other minerals, especially actinolite, chlorite, talc, compact felspar, steatite, garnet, zircon, &c., enter into and sometimes considerably modify the aspect of granite. The colours vary: the felspar is red, gray, yellow, white, green; the quartz is usually clear white or gray; the mica is black, gray, white, brown, and in various degrees silvery; the hornblende is dark green or black. The mica and felspar are invariably, and often (especially in cavities) beautifully crystallised; the quartz commonly fills the interstitial spaces left by these minerals, but small pyramidal crystals of quartz in great perfection may be sometimes seen imbedded in the faces of the prismatic felspar crystals, which are also sometimes penetrated by the filmy plates of mica.

Except in the veins which ramify into stratified rocks, and there grow fine-grained and even compact (like the base of some porphyries), granite, as its name implies, shows the grains of its component parts: the size of these varies extremely. The mica in the granite of Rubieslaw, near Aberdeen, forms laminæ some inches across; but in that of Cornwall, Skiddaw, &c., it exists in small plates; the felspar in graphic granite is almost one huge crystallised mass; large detached crystals in the granites of Shap and Ben Nevis make those rocks porphyritic, but in some of the building granites of Aberdeen all the ingredients are in small grains.

The proportion of the ingredients in typical granite varies greatly: the mica is sometimes absent, or replaced by hornblende. The following is a general view of the most remarkable granitic mixtures, to which some authors apply distinctive names, but we think with little advantage to geology. Some of these, mineralogically speaking, are identical with rocks of the trap family [SYENITE], but certainly occur as parts of a granitic series, viewed geologically. (M'Culloch, 'On Rocks.')

Binary Granite, composed of two ingredients: — as felspar and mica, quartz and felspar, either equally blended (as in Muncaster Fell, Cumberland), or in segregated portions (as the graphic granite); quartz and hornblende (M'Culloch); felspar and hornblende.

Granite of three ingredients (the typical varieties):—
- Quartz, felspar, and mica, uniformly blended, or with distinct additional crystals of felspar, then called Porphyritic Granite.
- Quartz, felspar, and hornblende. (Syenite of authors.)
- Quartz, felspar, and mica. (Instead of the mica, chlorite or talc sometimes appears.)

Granite of four ingredients:—
- Quartz, felspar, mica, and hornblende, or actinolite. (Syenite of some authors.)
- Quartz, felspar, mica, and compact felspar, or porcelain clay.
- Quartz, felspar, hornblende, and chlorite, or steatite.

GRAPE-HYACINTH. [MUSCARI.]

GRAPE-VINE. [VITIS.]

GRAPHIDACEÆ. [LICHENS.]

GRAPHIS. [LICHENS.]

GRAPHITE, *Plumbago, Black Lead.* This substance occurs crystallised and massive. Primary form a rhomboid. Occurs in imbedded hexagonal prisms. Cleavage parallel to the terminal planes of the prism, very distinct, and the laminæ flexible. Fracture granular and uneven. Hardness 1·0 to 2·0. Colour steel or blackish-gray. Streak black, shining. Lustre metallic and glistening. Unctuous to the touch. Opaque. Specific gravity 2·08 to 2·45.

Found in Greenland and in the neighbourhood of Philadelphia in the United States.

The massive varieties occur amorphous, in reniform masses and irregular nodules. Structure foliated, granular, compact.

Found in various parts of the world. That of Borrowdale in Cumberland is of the best quality for what are called black-lead pencils; while the commoner sorts are used for making melting-pots, for diminishing the friction of machinery, and for protecting iron from rusting. That which is imported from the East Indies is remarkably soft. Plumbago conducts electricity, is infusible, and very difficult of combustion.

Professor Vanuxem has analysed several varieties of Graphite. No. 1 was a pure specimen from Borrowdale, and No. 2 from Bustletown, Pennsylvania.

	No. 1.	No. 2.
Carbon	88·37	94·4
Silica	5·10	2·6
Alumina	1·00	—
Water	1·23	0·6
Oxides of Iron and Manganese	3·60	1·4
	99·30	99·0

It was at one time supposed that Graphite was a carburet of iron, but, in the opinion of Berzelius, the experiments of Karsten have proved that it is a peculiar form of carbon, and that the substances which it contains are in a state of mixture merely and not of chemical combination.

According to Dr. Thomson, Graphite is found usually in primary or transition rocks. At Borrowdale it occurs in nests in a greenstone rock, which constitutes a bed in clay-slate. In Inverness-shire it occurs in gneiss; at Arendal in Norway, in quartz-rock; and in the United States, in felspar and mica-slate, but always in primary rocks.

The material for lead-pencils, when of the finest quality, is first calcined and then sawn up into strips of the requisite size, and commonly set in wood (usually cedar) as they appear in the market. It is much used now in small cylinders, without wood, for ever-pointed pencil-cases. Graphite that cannot be thus used for pencils is reduced to a powder, and on being submitted to pressure it is made to adhere into a solid mass, which is subsequently cut up in the way referred to above. Graphite is also added to clay for making a kind of pottery. It is also extensively employed for diminishing the friction of machinery, also for the manufacture of crucibles and furnaces, which withstand a great heat. For this purpose it is mixed with half its weight of clay. It is also employed as a wash for giving a gloss to iron-stoves and railings.

GRAPSIDÆ, *Grapsoidians*, a tribe of Brachyurous Crustaceans belonging to the family of *Catametopes*, placed by M. Milne-Edwards between the Gonoplacians and the family of the Oxystomes, and approaching in his opinion nearer to the tribe of Gonoplacians than to the Ocypodians. He gives the following as the characters of the Grapsoidians:—

Carapace in general less regularly quadrilateral than in the Gonoplacians and Ocypodians: its lateral borders are nearly always slightly curved, and its fronto-orbital border frequently does not occupy more than about two-thirds of its transversal diameter. The body is nearly always compressed, and the sternal plastron but little or not at all curved from before backwards. The front is nearly always strongly recurved, or rather bent down, and very wide, occupying about the half of the anterior border of the carapace, and exceeding on each side the edge of the lateral borders of the buccal frame. The orbits are oval-shaped and of moderate size; and the lateral borders of the carapace are slightly curved and nearly always trenchant. The ocular pedicles are large and short; their insertion is below the front, and the cornea occupies one-half of their length. The internal antennæ are sometimes vertical and lodged in distinct pits (fossettes), which are open at the upper surface of the carapace; but in the great majority of instances these organs are entirely transversal and completely covered above by the front; their terminal stem is nearly always of the ordinary length, and terminated by elongated and multiarticulate appendages which are very distinct. The external antennæ here fill the gap which exists between the front and the inferior orbital border, and which forms a communication for the antennary pits with the orbits. Their first joint is nearly always short, but rather large, and nearly entirely covered by the front. The three following joints and the terminal stem are very little developed. The anterior border of the epistome is always placed on the same line as the inferior border of the orbit, with which it is continuous. The buccal frame is but little or not at all narrowed in front, and the terminal stemlet of the external jaw-feet always springs from the middle of the anterior border, or from the external angle of the preceding joint, and is never hidden below it. The palp of these jaw-feet presents nearly the same form as in the crabs; it is large, and terminated by a multiarticulate appendage bent back inwards under the third joint of those members. The sternal plastron is not very wide backwards, and gives insertion to the intromissive organs. The disposition of the feet varies; those of the first pair are in general short, and those of the four last pairs are very much compressed; these last are sometimes natatory, a character which is not met with in any other crustacean of this family. The abdomen is composed of seven joints, and its second articulation extends nearly always, in both one and the other sex, as far as the origin of the posterior feet. The thoracic branchiæ generally amount to seven on each side. The epimere of the last thoracic ring is nearly as much developed as that of the preceding ring, and concurs to form the vault of the flanks; thus the superior or epimerean cellule of this penultimate ring does not cover the cellule which corresponds to the posterior foot, as is the case in the Gecarcinians.

The greater numbers of the tribe, as far as the manners of the crustaceans composing it are known, live on the shore, or on the rocks which border the coasts; they are very timorous, and run away with much swiftness.

M. Milne-Edwards, who gives the above definition and account of the Grapsoidians, divides the tribe into seven genera, namely:—

Sesarma (Say).—Carapace quadrilateral, nearly equilateral generally, and very much elevated in front; fronto-orbital border occupying its whole width; lateral borders straight, and posterior border very long. Front nearly always suddenly bent down, and its length very considerable, exceeding half of the transversal diameter of the carapace. Eyes large and of moderate length; orbits inclining to oval, with generally at their external angle a large gap, which is continued with a horizontal gutter situated immediately below the lateral border of the carapace, a character found in *Macrophthalmus*, but which does not exist in the majority of the Grapsoidians; lower border of the orbit horizontal and directed forwards; a very strong tooth is directed towards the front from its internal part. Antennary pits transversely oval, and the space which separates them generally very large. Basilary joint of the external antennæ more or less cordiform, giving insertion to the succeeding joint in a notch situated in the middle of its internal border; its width is considerable, although the front exceeds it laterally. Epistome very short and projecting, like all the surrounding parts; it is continued with the inferior orbitary border, and below that border there is a horizontal gutter which terminates at the angle of the buccal frame; there are also other furrows under the pterygostomian regions, the surface of which is granulous or reticulated; it is generally divided into small squares of great regularity, and this character alone would suffice to distinguish the greater part of the species of *Sesarma* from nearly all the other *Catametopes*. The disposition of the external jaw-feet is also very remarkable; for there is always a wide lozenge-shaped space between them, and their third joint longer than it is wide, and longer than the second, is rather oval, and but little or not at all truncated anteriorly. It is also to be noted that there exists on the surface of this lamellar portion of the external jaw-feet a projecting line or crest which is carried obliquely from its external and posterior angle to its interior (anterior?) and internal angle; this crest is generally furnished with hair, and there is a deep furrow near its external border. The sternal plastron is generally convex from behind forwards, and in the male the anterior portion of the cavity which receives the abdomen is rounded and surrounded with a small border. The anterior feet of the male are nearly always much longer than those of the second pair, and terminated by a strong and convex hand. Sometimes it is the same with the female. The feet of the second pair are shorter than those of the third, and terminate, like all the succeeding feet, by a large rounded styliform joint which is more or less distinctly canaliculated, generally downy, and almost always completely devoid of spines. The second ring of the abdomen is in general nearly linear, and the last is much more narrow at its base than the penultimate ring, so that at this point the abdomen is abruptly narrowed. In the female the last joint of the abdomen is very small, and in general lodged almost entirely in a notch of the preceding ring.

The species of this genus are found upon the coasts of America, Africa, and Asia.

Mr. Say, who first separated these crustaceans under the generic name *Sesarma*, afterwards reunited them to *Grapsus*; but M. Milne-Edwards, who has entered into the details of the construction of *Sesarma* above given, in order to point out its distinctions, is of opinion that it ought to be distinguished, and to be considered as constituting the type of a rather numerous genus, which the latter divides into the following sections:—

A. Species whose carapace is at least as wide as it is long, and but little or not at all narrowed posteriorly.

a. Lateral borders of the carapace armed with two or three teeth (comprising the external orbital angle). Body very thick, especially before.

S. tetragona (*Cancer tetragonus* (?), Fabr.; *C. fascicularis*, Herbst; *Ocypode tetragona*, Olivier; *Grapsus tetragona*, Latreille). Length 28 lines. Locality, Indian Ocean.

a a. Lateral borders presenting no tooth behind the angle of the external orbit. Body depressed.

S. quadrata (*Cancer quadratus*, Fabr.; *Ocypode plicata*, Bosc.) Length, 8 lines. Locality, the neighbourhood of Pondicherry.

B. Species whose carapace is much longer than it is wide, and strongly narrowed backwards.

S. Pisonii (*Arata pinima* of Piso). Length, 8 lines. Locality, the Antilles. M. Milne-Edwards says that Latreille has confounded this species with *Grapsus cruentatus*. M. Milne-Edwards is also of opinion that *G. Husardii* (Desmarest) and *Cancer Hispanus* (Herbst) belong to this genus.

Cyclograpsus (Milne-Edwards).—Body much less flattened than in *Grapsus* and wider, the transversal diameter of the carapace much exceeding its length. Front inclined, but far from being vertical. Lateral borders of the shell elevated, delicate, and very much curved, and its lateral walls forming ordinarily a nearly straight angle with its upper surface. Eyes nothing remarkable; orbits directed forwards and presenting almost always below their external angle a wide and deep notch, which, as in *Sesarma*, is continued backwards with a transversal gutter hollowed out in the pterygostomian regions of the carapace below its lateral border. Antennary pits much less narrow than in *Grapsus*, and the basilary joint of the externa antennæ much less wide. External jaw-feet much resembling those of *Grapsus*: their third joint shorter than the second, wide as it is long, enlarged anteriorly and strongly truncated at its anterior border; a small projecting and piliferous crest runs obliquely from the anterior and interior angle of this joint to the posterior and external angle of the preceding joint, so as to form with that of the opposite side a triangle, the base of which is backwards; the external appendage of these jaw-feet nearly reaches the anterior border of the third joint of their stem, and terminates by a multiarticulate appendage. Feet of nearly the same form and disposition as in *Grapsus*, except that the tarsus is not so large, and has no spines.

The species are distributed in the seas of Asia exclusively. (Milne-Edwards.)

M. Milne-Edwards divides the genus into the following sections:—

A. Species having the lateral border of the carapace entire.

a. A deep gutter springing from the external orbital gap and directed forwards.

C. punctatus. Length, 15 lines. Locality the Indian Ocean.

a a. No well-marked post-orbital gutter.

C. integer (*Grapsus integer*, Latreille). Length, 4 lines. Locality Brazil.

B. Species the lateral border of whose carapace is dentated.

b. External orbital gap but little marked. Orbits directed forward.

C. quadridentatus. Length, 10 lines. Locality, Australia.

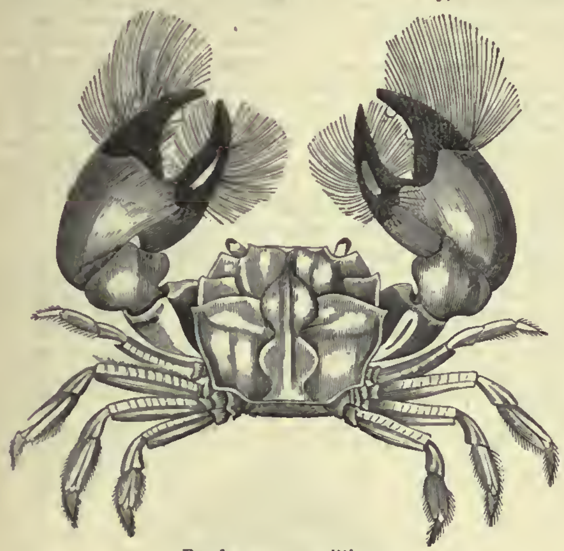
b b. External orbital gap very wide. Orbits very oblique.

C. Latreillii (*Grapsus venosus*, Latreille). Length, 4 lines. Locality, Mauritius.

Pseudograpsus (Milne-Edwards).—M. Milne-Edwards observes that one of the characters pointed out with reason by M. Latreille as distinguishing the natural groups of *Grapsus* and *Plagusia* is the having the external jaw-feet narrow and notched on their internal border, so that these organs, instead of closing the mouth completely, leave between them a vacant lozenge-shaped space; but he remarks that this disposition is not met with in all the species which are usually arranged under the genus *Grapsus*; and as these modifications of the buccal apparatus coincide with other characters, and seem to indicate a natural division among these animals, he has taken it as the basis of their classification, and proposes for those walking Grapsoidians whose mouth is completely closed by the external jaw-feet the name of *Pseudograpsus*, with the following generic character:—

General form approaching that of *Cyclograpsus* more than that of the other Grapsoidians, the body being thick, and the carapace, convex above, being rather regularly rounded on the sides. Basilary joint of the external antennæ nearly square and joined to the front, its external border being in contact with a vertical tooth which elevates itself on the floor (plancher) of the orbit, as in *Macrophthalmus* and the Ocypodians. Internal border of the second and third joint of the external jaw-feet straight, and this last joint, remarkable for being much wider than it is long, presents in the middle of its anterior border a notch whence springs the terminal stemlet (tigelle). Sternal plastron nearly circular, and slightly curved from before backwards. Anterior feet of the male very large, and much longer than any of the succeeding feet, which are rounded and terminated by a hairy tarsus, and completely deprived of spines. Abdomen of the male extending quite to the base of the posterior feet, and its second joint linear. The species are found in the Asiatic seas.

P. penciliger (*Cancer setosus* (?), Fabricius; *Grapsus pencilliger*, Latreille). The feet are rounded and furnished with a thick-set down. Length, rather more than an inch. Locality, seas of Asia.



Pseudograpsus pencilliger.

Grapsus (Lamarck, in part).—M. Milne-Edwards retains in this genus those species which are, for the most part, remarkable for the extreme flatness of the body, and present the following characters :—

Upper surface of the carapace always nearly horizontal and nearly square; its anterior border rarely occupies its whole width, but the difference is not considerable, and in general its posterior part is not narrowed—the lateral borders are delicate, and ordinarily a little curved. Stomachal region very large, and branchial regions very extended, and nearly always marked with salient oblique lines. Front very wide, and inclined or even completely bent down; the upper part, in general, divided into four lobes, which often become very projecting. Orbits deep, and their inferior border at least as salient as the superior border, but the external extremity does not open into a horizontal gutter situated under the lateral border of the carapace, as in *Sesarma*, and presents one or two small notches at most; the tooth which elevates itself from their lower wall, beneath the articulation of the eye, is in general very strong. Disposition of the antennæ nearly the same as in the preceding genus, except that the antennary pits are in general less wide, and separated by a narrow space between them. External jaw-feet strongly notched within, so as to leave between them a large vacant lozenge-shaped space; their third joint is trapezoidal, and terminates anteriorly by a straight and very wide border; it is in general nearly of the length of the second joint, and carries the succeeding joint at its external angle, but it is sometimes very short, strongly dilated on the external side, and gives insertion to the fourth joint towards the middle of its anterior border. Pterygostomian regions smooth, or very slightly granulous, and never presenting the disposition so remarkable in *Sesarma*. Feet of the first pair short, the arm enlarged and spiny within, hands short but rather stout in the males. The succeeding feet remarkably flattened; their third joint entirely lamellar below in its external moiety, its superior border delicate and elevated, and the tarsus large and very spiny. Second pair of feet much shorter than the third, which, in their turn, are in general much shorter than the penultimate feet. Abdomen of the male triangular; that of the female very wide, its last joint large, and not inclosed in a notch of the preceding joint, as in *Sesarma*.

Grapsus, as above modified, is spread over nearly all parts of the world. The known species generally inhabit rocky coasts, and run with great rapidity.

A. Species having the third joint of the external jaw-feet longer than it is wide, and without any remarkable dilatation towards the external angle.

G. pictus (*Pagurus maculatus*, Catesby; Cangrejo de Arrecife, Parra; *Cancer tenuicristatus*, Herbst; *Cancer grapsus*, Fabricius; *Grapsus pictus*, Latreille). Length, rather more than 2 inches. Colour red, with irregular yellow stains. Locality, the Antilles.

Catesby gives the following account of the habits of this species under the name of *Pagurus maculatus*, the Red-Mottled Crab :—"These crabs inhabit the rocks hanging over the sea; they are the nimblest of all other crabs; they run with surprising agility along the upright side of a rock, and even under rocks that hang horizontally over the sea; this they are often necessitated to do for escaping the assaults of rapacious birds which pursue them. These crabs, so far as I could observe, never go to land, but frequent mostly those parts of the promontories and islands of rocks in and near the sea, where, by the continual and violent agitation of the waves against the rocks, they are always wet, continually receiving the spray of the sea, which often washes them into it; but they instantly return to the rock again, not being able to live under water, and yet requiring more of that element than any of the crustaceous kinds that are not fish."

M. Milne-Edwards remarks that Messrs. Quoy and Gaimard brought from the Sandwich Islands a *Grapsus* which bears a strong analogy to *Grapsus pictus*, but which, it appears to him, ought to be distinguished from it, on account of the great number of little conical hairs disposed in small transversal ranks on the branchial and stomachal regions, the greater extent of the front, and some other characters; but as he had not examined more than one individual in a bad state of preservation, and as *Grapsus pictus* presents considerable individual differences, he cannot pronounce on the distinction decidedly, but notes the fact on account of its interest in regard of zoological geography. He observes that in the collection of the Paris Museum he has designated this crustacean under the name of *Grapsus rudis*, and that it is probably the species figured by Messrs. Quoy and Gaimard under the name of the Painted Grapsus. ('Voyage de M. Freycinet,' pl. 76, fig. 2.)

B. Third joint of the external jaw-feet as wide as it is long, and dilated outwards towards the anterior angle.

G. varius (Cancre Madrè (?), Rondelet; *Cancer marmoratus*, Fabricius; *Grapsus varius*, Latreille). Length about 18 lines. Colour violaceous-red, variegated with small irregular yellowish stains. Locality, the rocky parts of the coasts of Bretagne, Italy, &c. (very common).

Nautilograpsus (M. Edwards).—Differing but little from *Grapsus*. Carapace, instead of being wider than it is long and nearly flat, as in *Grapsus*, longer than it is large, and convex above. Regions not distinct. Front advanced, lamellar, and simply inclined. Lateral borders curved and long. Internal border of the second joint of the jaw-feet nearly straight, and the third joint even longer than in *Grapsus varius*, but nearly of the same form. Feet much shorter than in *Grapsus*. The intromissive organs of the male traverse a simple notch of the border of the sternal plastron. For the rest resembling the *Grapsi* of the second division.

The single species known is found in all latitudes and met with far at sea, often floating on *Fucus natans*, or on large marine animals.

N. minutus (*Cancellus marinus quadratus*, Sloane; Turtle-Crab, Browne; *Cancer minutus*, Fabricius; *Grapsus minutus*, Latreille; *Grapsus cinereus*, Say; Grapse Unie, Lamarck—Gal. du Mus.). Length from 4 to 8 lines, varying much in colour. M. Milne-Edwards says that he sees no sufficient reason for distinguishing this species from *Grapsus testudinum*, Roux.

Grapsus pictus.

Plagusia (Latreille). — Resembling *Grapsus* generally, but distinguished at once by a singular disposition of the internal antennæ not met with in any other brachyurous decapod, according to M. Milne-Edwards. These organs, instead of being bent back under the front, are each lodged in a deep notch in this part, so as always to be uncovered superiorly. Carapace broad and flattened, its anterior border occupying only one-half of its width, which is most extended towards the level of the last pair of feet but one. Portion of the front between the antennary pits triangular and curved downwards. Eyes short and large; orbits directed forwards and upwards, and separated from the antennary pits. Internal antennæ vertical; external antennæ occupying the internal angle of the orbit, and nearly of the same form as in *Grapsus*. Anterior border of the buccal frame very projecting, and continuous with the lower orbital border. The external jaw-feet close the mouth completely, and are not notched within as in *Grapsus;* they are in form generally very nearly the same as in the Crabs and *Portunus;* the third joint is much shorter than the preceding one, nearly square, and notched at its anterior and internal angle for the insertion of the succeeding joint. Sternum very wide and deeply notched backwards for the reception of the abdomen. Anterior feet generally moderate in the male and small in the female; claws ordinarily with a spoon-shaped termination; succeeding feet disposed as in *Grapsus;* sometimes the third, sometimes the fourth pair longest; they are in general ciliated on the superior border, and the tarsus is always armed with strong spines. Abdomen and branchiæ as in *Grapsus*.

Plagusia belongs more particularly to the Indian Ocean, and is found from the Cape of Good Hope to Chili. (M. Edwards.)

A. Species having the superior border of the last eight feet armed with teeth nearly throughout its length.

P. clavimana (*Cancer planissimus*, Herbst). Length rather more than an inch: antepenultimate ring of the abdomen soldered to the preceding ring in both sexes. It is found in Australia, and Vanicoro, New Zealand.

Plagusia clavimana.

B. Species whose last four pair of feet are not armed above with more than a single tooth placed near the extremity of the upper border of their third joint.

P. depressa (*Cancer depressus*, Herbst; *Grapsus depressus*, Latreille; *P. immaculata*, Lamarck; *P. depressa*, Latreille). It is a native of the Indian Ocean, seas of China, New Guinea, &c.

M. Milne-Edwards observes that the specific name of this *Plagusia* is badly chosen, inasmuch as it is less flattened than the greater part of the species. He is also of opinion that *P. depressa* of Say ('Acad. Philad.,' tom. i. p. 100) appears to be nearer to *P. squamosa* than the species here mentioned, but he thinks that it ought probably to be distinguished from it.

Varuna (M. Edwards).—Carapace very much depressed and nearly quadrilateral, but the lateral borders arched. Front wide, straight, and trenchant. Orbits approaching to oval; a fissure on their superior border, their external angle very salient, and hardly any inferior border. Internal antennæ bent back a little obliquely outwards, and their pits completely separated from the orbits by the basilary joint of the external antennæ, which joins the front, and presents nothing remarkable. Epistome larger than it is in the greater part of the Grapsoidians, and external jaw-feet nearly joining it; their internal border is nearly straight, and the third joint, very much dilated externally, carries the following joint towards the middle of its anterior border, which is very large and notched. Anterior feet large; and the succeeding feet, instead of terminating by a large and cylindrical or styliform tarsus, as in the other Grapsoidians, with their last joint wide, flattened, ciliated on the edges, and lanceolate. Abdomen of the male with seven distinct joints.

V. litterata (*Cancer litteratus*, Fabricius; *Grapsus litteratus*, Bosc.). Locality, Indian Ocean.

GRAPSUS. [GRAPSIDÆ.]

GRAPTO'LEPIS, a genus of Fossil Ganoid Fishes, from the Carboniferous system of Carluke. (Agassiz.)

GRAPTO'LITHUS (literally 'written-stone'), a name used by Linnæus chiefly to include appearances in stones resembling drawings—as of maps, ruins, vegetable forms, &c. Thus the Florentine, or Ruin Marble, the dendritical ramifications on many limestones, and the moss-like forms in agates, &c. were ranked as Graptolites.

Among the species included by Linnæus is one resembling *Algæ*, from the Transition Strata of Gothland.

GRASSHOPPER. [GRYLLIDÆ.]

GRASSHOPPER-WARBLER. [SALICARIA.]

GRASS-MOTHS. [CRAMBUS.]

GRATELU'PIA, a genus of Conchiferous *Mollusca*, established by M. Charles Desmoulins, for a fossil bivalve which had been confounded by M. de Basterot with the genus *Donax*, under the name of *Donax irregularis*. But one species, *Gratelupia donaciformis*, was known (from Bordeaux, Miocene Formation of Lyell), till Mr. Lea discovered a second in the Claiborne Tertiary (Eocene of Lyell), which he has named *Gratelupia Moulinsii*, after the founder of the genus. Diameter 1 inch, length 1·4, breadth 1·9. It has the following characters:—Animal unknown. Shell subtrigonal, equivalve, regular, nearly equilateral, a little attenuated at its posterior part, and presenting at the postero-inferior border a slight sinuosity. Umbones very small, projecting but little, and hardly inclined forwards. Hinge consisting of three cardinal divergent teeth in each valve, and of from three to six cardini-serial teeth converging towards their summits, lamellar, with their edges finely dentilated, and situated a little behind the summit, under the ligament; a single lateral anterior tooth under the lunule in the left valve, corresponding with a pit similarly situated in the right valve; external ligament long, convex, overpassing the serial teeth. Muscular impressions nearly equal, oval, united by a pallial impression largely and very deeply excavated backwards.

The genus was named by M. C. Desmoulins after Dr. Grateloup.

Gratelupia Moulinsii. (Lea.)

GRAUWACKE (or Graywacke, as it is often written in English works on geology), a German term applied to some of the ancient stratified rocks, which has been with some unwillingness admitted by English geologists, either in the original sense, signifying a particular kind of rock, or as typifying a group or series of strata in which such rocks form a conspicuous portion.

In the former sense Grauwacke Rocks may be considered as having almost the same relation to clay-slates that argillaceous sandstones and conglomerates bear to common clays; for argillaceous slate, by including rolled fragments or minute grains of quartz-sand, with or without mica, becomes the grauwacke and grauwacke slate of Werner and his followers. When the sand or gravel predominates so as nearly to exclude the argillaceous cement, the distinction between grauwacke and sandstone is almost imaginary, just as, on the other hand, indurated shale and soft clay-slate are not always certainly distinguishable. In the pass of Lennie, above Callender, in the Lammermuir Hills, in the primary series of rocks near Cavan in Ireland, and in Snowdon, the student may study examples of the genuine grauwacke of the German writers; while fine-grained sandy rocks, corresponding to the title of grauwacke slate, are common in Westmoreland, Cumberland, Wales, the Isle of Man, the Lammermuir Hills, &c.

Viewed geologically, the Grauwacke Rocks lie in the midst of the primary argillaceous strata, and constitute a part of the 'transition series' of the continental geologists. The 'grauwacke group' of Sir Henry De la Beche includes the Silurian Rocks of Sir Roderick Murchison, and a portion of the older strata designated as Cambrian Rocks by Professor Sedgwick. [GEOLOGY.] It is uncertain whether the term 'grauwacke' will in future be used merely to characterise rocks of a certain kind lying in the Cambrian or other series of argillaceous schists, or be allowed collectively to represent a geological group of strata.

Mr. Conybeare ('Reports of the British Association') is desirous of substituting for this somewhat rude term the more learned name of clasmoschist (κλάσμα, a fragment). M. Brongniart includes many varieties of grauwacke and grauwacke slate under the term psammite (ψάμμος, sand). [GEOLOGY; ROCKS; STRATIFICATION.]

GRAVEL. The small fragments of rocks which have been drifted by any forces of water over the surface of the earth are usually designated by this general term, which is happily free from any hypothetical meaning. Many parts of the surface of the earth are so covered. From the geographical phenomena, mode of accumulation, and other circumstances, the mode of action of the water may be often completely determined. It is certain that much of the undulated surface of the land has been traversed by powerful currents of water in directions different from those of the fresh-water streams now running; that in other cases the sea has acted on the land at greater heights and under different circumstances from what we now behold; and as a great part of the evidence for this is to be collected from the study of gravel deposits, we see how important is a right knowledge of the facts concerning these in repressing vain speculation and directing sound inferences. Whether the gravel observed at any spot was transported along the natural drainage hollows of the surface may be often certainly known by inspection of the nature of the fragments and the examination of the physical geography of the country in which they occur. Whether the waters descending these valleys performed the effects while flowing at higher levels, under the influence of dams, lakes, or other peculiarities, may also often be determined by suitable examination.

It will often be thus found that the gravel was not transported down the existing drainage hollows, but across hills and valleys, lakes, and arms of the sea. Under existing circumstances no ordinary action of nature can occasion such effects; it is therefore a question of great importance whether in ancient times the circumstances of physical geography were so different as to allow of the effects being performed by ordinary action, or whether an extraordinary action must be appealed to. The latter opinion has been held by diluvialists, reasoning on the distribution of gravel and large boulders of rock dispersed from the Alps and the Cumbrian Mountains; but various attempts have been made to explain the phenomena by supposed changes of physical geography, the aid of icebergs, &c. For determining this and such questions it should be examined—whether the gravel, &c., contains remains of organic beings; whether these are of land quadrupeds, land shells, land plants, or marine shells, bones of whales, dolphins, &c., in order to know whether the currents of water were derived from surface drainage or the movement of the sea. It is important to find out whether the gravel was deposited in still or agitated, in deep or shallow water, in lakes, flood-channels, or the sea: whether it now rests in included hollows, or in insular hills;—whether marine deposits of gravel alternate with others attributed to fresh-water currents;—whether gravel of local origin lies over or under other gravel brought from a distance.

GRAYHOUND, a variety of Dog remarkable for the keenness of its sight, the symmetrical strength and beauty of its form, and its great swiftness in the chase. There are many varieties of the Grayhound, from the Irish Grayhound and Highland breed (the latter made familiar to us by the pen of Sir Walter Scott and the pencil of Edwin Landseer), to the smoothed-haired southern breed, and that pretty pet, the Italian Grayhound.

In ancient times the Grayhound was one of the three animals whose presence marked the possessor to be a nobleman or gentleman; and we find it recorded as being accepted by kings in payment, as in the case of the fine paid to King John, consisting of "500 marks, 10 horses, and ten leashes of Grayhounds."

Formerly this hound was principally employed in chasing the stag. Thus Queen Elizabeth was gratified one day, after dinner, by seeing from a turret sixteen deer pulled down by Grayhounds upon the lawn at Cowdrey Park in Sussex; and the old ballads, 'Chevy Chase' among others, speak of their being used for the same sport in earlier times.

The well-known old lines descriptive of the perfections of a Grayhound have never yet been superseded:—

"Headed lyke a snake,
Neckyed lyke a drake
Fotted lyke a catte,
Taylled lyke a ratte;
Syded lyke a breme,
And chyned lyke a beme."

In modern times, many distinguished sportsmen (the earl of Orford in particular, who is said to have died on the field where his favourite bitch Old Czarina won a great match) have paid much attention to the breed, and have been rewarded by some of the best dogs ever seen. Major Osbaldeston, Major Topham, and Colonel Thornton were among those who were celebrated for the pure blood and admirable powers of their Grayhounds. The names of Czarina, Jupiter, Claret, Snowball, the Miller, Schoolboy, and Major, together with many others of note, are still familiar to those who attend the great coursing meetings. We refer the reader who is interested to 'The Sportsman's Cabinet,' 'Rural Sports,' 'The Courser's Manual,' 'The Sporting Magazine,' and similar works, for further information.

The Grayhound is supposed to have reached his full growth when two years old, and to be on the decline from his fifth or sixth year, when he is apt to begin to 'run cunning.' Dame Juliana Berners gives a greater latitude, making nine years the point at which he becomes too old for service:—

"And when he comes to that yere,
Have him to the tannere,
For the best whelp ever bitch had,
At nine years is full bad."

Sir Walter Scott, who quotes these lines, well vindicates the character of the Grayhound for intelligence, attachment, and sagacity, qualities which some, without any good reason, have denied to this noble race. [Dog.]

The Grayhound seems to have been a distinct variety of the Dog from a very early period in the history of this species. It exists at present in Egypt, and seems to be represented in the old Egyptian paintings. It is probable also that this was the form of dog with which the ancient Hebrews were best acquainted. We annex a representation of this dog from a drawing by Colonel Smith.

Arabian Grayhound.

GRAY-LAG. [Ducks.]

GRAYLING, a fish of the Salmon tribe, inhabiting many of the streams of England, in some of which it is abundant. It is also found in Sweden, Norway, and Lapland. [Salmonidæ.]

GRAYSTONE, a term proposed by Mr. Poulett Scrope to include certain volcanic rocks composed of felspar, augite, or hornblende, and iron; the felspar being sometimes replaced by leucite, or melilite.

GRAYWACKE. [Grauwacke.]

GREBE. [Colymbidæ.]

GREENBONE, two of the common Fish of our shores (the Gar-Fish (*Belone vulgaris*), and the Viviparous Bleny (*Zoarces viviparus*). [Belone; Zoarces.]

GREEN-FINCH. [Coccothraustes; Loxia.]

GREEN-IRON-EARTH, also called Hypochlorite, is a Mineral occuring in reniform, botryoidal, and globular masses. Its colour is green, passing into black and yellow. Lustre resinous and dull. Brittle. Found at Schneeberg in Saxony. The following is its analysis by Schular:—

Silica	50·24
Oxide of Bismuth	13·03
Alumina	14·65
Oxide of Iron	10·54
Phosphoric Acid with traces of Manganese	9·62
	98·08

GREENOCKITE, a Mineral, consisting of Sulphuret of Cadmium. It occurs crystallised in 6-sided prisms, with 6-sided pyramids. Hardness 2·75. Lustre vitreous, sometimes almost adamantine. Translucent to transparent. Specific gravity 4·842. Found at Bishoptown, Renfrewshire, and on the Cochuo-Burn, on the north side of the Clyde. The following is its analysis by Connell:—

Sulphur	22·56
Cadmium	77·30
	99·86

GREENOVITE, a Mineral, occurring in small amorphous crystalline masses. Primary form a doubly oblique prism. Colour deep rose-red. Hardness greater than that of fluor-spar; does not scratch glass. Some of the faces are brilliant, others often dull and tarnished. Specific gravity 3·44. It is found at St.-Marcel in Piedmont. Analysis, by M. Delesse:—

Silica	30·40
Oxide of Titanium	42·
Lime	24·30
Protoxide of Manganese	3·80
	100·50

M. Delesse observes that this mineral is analogous to *Sphene*.

GREENSAND. [Chalk Formation.]

GREENSHANK, the common name for a well-known Wading Bird, referred by some ornithologists to the Godwits; by others to the Snipes. [SCOLOPACIDÆ.]

GREENSTONE. Rocks in which felspar is combined with hornblende, or less commonly augite, the mixture being evident and the ingredients distinct, are usually called Greenstone. In such rocks the felspar is usually white or greenish, and less completely crystallised than in sienite; grains of pyrites frequently occur; the masses have a rude prismatic figure (Corygills, Isle of Arran); and by decay show a globular interior structure as in basalt. [BASALT.] If augite and hornblende be in effect the same mineral generated under different circumstances, and hypersthene be analogous, if not identical, it is perhaps probable that geologists may hereafter be disposed to adopt a suggestion of Dr. M'Culloch, and divide sienites, greenstones, and basalts according to the substance united with felspar, which is present in all. We shall then have hornblendic sienite, greenstone and basalt, augitic sienite, greenstone and basalt, hypersthenic sienite, greenstone and basalt, the distinctions between sienite, greenstone, and basalt being chiefly founded on the aggregation of the rock and the character of the felspar. The geological history of greenstone is very similar to that of basalt, and in the same tract of country one quarry may give fine-grained basalt and another distinctly marked greenstone. [ROCKS; BASALT; AUGITE; HORNBLENDE; TRAP.]

GRES. This French equivalent of the English word grit, or sandstone, includes several rocks, which may be thus noticed:—

Grès de Fontainebleau . . .	A tertiary rock.
Grès de Vienne Grès des Carpathes	Equivalent of the greensands.
Grès de Luxembourg . . .	Between the lias and the variegated marls.
Grès bigarré	Equivalent of the hunter sandstein (German,) and new red-sandstone (English).
Grès Vosgien . .	A local red grit rock on the flanks of the Vosges Mountains.
Grès rouge (Grès ronge) . . .	The sandstone below the magnesian limestone (termed rother sandstein in some parts of Germany, also called rothe todte liegende).
Grès houillier	Grits of the coal formation.

GRENGESITE, a Mineral, consisting of hydrous silicate of iron.

GREVILLEA, a genus of Proteaceous Plants named by Robert Brown in honour of Dr. Greville of Edinburgh.

GRE'WIA, a genus of Plants belonging to the natural order *Tiliaceæ*, so-named in honour of Dr. Grew, celebrated for his work on the anatomy of vegetables. Though the family takes its name from the European genus *Tilia*, its species are distributed chiefly through tropical countries. *Grewia* now consists of upwards of 50 species of moderately-sized trees or shrubs, which have leaves resembling those of the elm, yellow or white flowers, and many of them pleasant-tasted subacid fruit. The calyx consists of 5 coriaceous sepals, which are coloured internally. Petals 5, each provided with a gland or scale at the base, inserted with the numerous stamens into the elevated receptacle; germ superior, generally 2-celled; style single; stigma 4-lobed; drupe with from one to four 1- or 2-seeded small nuts. The species of *Grewia* are found in the tropical islands and the hot parts of the Old World, extending west to the west coast of Africa, and south to the Cape of Good Hope. In India they are common in every part, both in jungly forests and the dry open plains; some of the same species extend from the southern to the most northern parts; a few even ascend the Himalayas to moderate elevations. Species are also found in Arabia and Egypt.

The species of *Tiliaceæ* are noted for their mucilaginous properties, as well as for the remarkable tenacity of the inner fibre of their bark, as exemplified in the *Tilia*, or common European lime-tree: that of *Grewia oppositifolia* is employed for making ropes with in the Himalayas; and *G. elastica*, figured by Dr. Royle in 'Illustrations of Himalayan Botany,' t. 22, and called Dhamnoo by the natives, is valued for the strength and elasticity of its wood. Cattle are fed on the leaves of some species, as *G. didyma*, at moderate elevations in the Himalayas. The pleasant-tasted subacid fruit of several species is eaten by the natives of India, but principally used for making sherbet. *Grewia asiatica*, or *phalsa*, is that principally employed and cultivated in their gardens.

GRIAS, a genus of Plants belonging to the natural order *Myrtaceæ*. It has the tube of the calyx adhering to the ovarium; the limb small, 4-cleft, obtuse; the petals 4, coriaceous; the stamens numerous, inserted in a square disc; the filaments joined into 5 series at the base; the inner ones very short; the anthers kidney-shaped, small; the style wanting; the stigma cruciate, hidden in the incurved stamens; the fruit ovate, 8-furrowed, crowned by the calyx. There is but one species, *G. cauliflora*, the Anchovy Pear. It is a tall little-branched tree with very long oblong leaves, and large white flowers seated on short many-flowered peduncles. It is a native of subalpine districts of Jamaica in boggy places. The fruit is an ovate berry the size of an alligator's egg, and of a brownish russet colour, and is pickled and eaten in the same way as the mango. It is readily propagated by seeds, and the young plants must be kept in a moist heat. It grows best in a loamy soil, and may also be propagated by large cuttings placed under a hand-glass in heat.

(Don, *Dichlamydeous Plants.*)

GRIFFON. [VULTURIDÆ.]

GRILSE. [SALMONIDÆ.]

GRIMOTHEA. [GALATHEIDÆ.]

GRI'SLEA, a genus of tropical Plants belonging to the natural order *Lythraceæ*, or *Salicariaceæ*. The genus is characterised by having a tubular calyx, which is from 4- to 6-toothed; the petals, 4 to 6 in number, are inserted between the divisions of the calyx; the stamens, twice as many, arise from the bottom of the calyx, and have their long filaments extending with the style beyond its tube; the capsule is superior, 2-celled, many-seeded, and covered by the persistent calyx. The plants of this genus consist of shrubs, with opposite, very entire leaves, dotted on the under surface with dark-coloured glands. The peduncles are axillary and many-flowered; the flowers reddish-coloured. The species are not more than three in number, of which one, *G. secunda*, is found in the warmer parts of South America, and the others in India. *G. tomentosa*, the best known and most useful species, is found in the islands of the Indian Ocean, in China, and in every part of the continent of India, especially in the jungly tracts at the foot of its several ranges of mountains. In such situations its bright red calyx, retaining its colour till the seeds are ripe, gives the whole plant a very showy appearance, and points it out to the collectors of its flowers, which form an article of commerce. These are much employed by the natives of India for dyeing a red colour, and having some degree of astringency, are also employed in Indian medicine. The plant is known by the names of Dharee, Dhaee, &c., and the flowers by that of Dhaeephool.

GRISON. [VIVERRIDÆ.]

GRISTLE. [CARTILAGE.]

GRIT. Hard sandstones are called Grits in the north of England, and indeed many soft sandstones are so termed. In particular districts some distinctive terms are applied, as millstone-grit, red-grit, white-grit, grindstone-grit, &c. Almost universally in the north of England the term 'freestone' belongs to such gritstones as will work easily and to a good face; 'calliard' stones are intractable, close-grained, almost flinty grits; in Aldstone Moor, Cumberland, the term 'hazel' is given to some hard grits; at Newcastle the word 'post' signifies a 'bed,' and is generally associated with gritstone rocks.

In geology the most remarkable rocks to which the word grit is applied, are—the calcareous grit (in which however there is often little of calcareous matter), a part of the middle oolite formation; the millstone grit, which contains beds of quartz pebbles, and is altogether a coarse irregularly laminated rock. [SANDSTONE.]

GRÖFYRITE, a Mineral consisting of hydrous silicate of alumina allied to Halloysite. [HALLOYSITE.]

GROMWELL. [LITHOSPERMUM.]

GROSBEAK. [COCCOTHRAUSTES.]

GROSSULARIACEÆ, *Currant-Worts*, a natural order of Exogenous Plants, consisting of 2 genera and 95 species. The genera consist of shrubs, either unarmed or spiny. The leaves alternate, lobed, with a planted vernation, often with a membranous edge to the base of the petioles. Flowers in axillary racemes, with bracts at their base, rarely unisexual by abortion; the calyx superior, 4- or

Ribes Grossularia.

1, a flower magnified; 2, the ovary and styles, from which the calyx, petals, and stamens have been cut off; 3, a calyx laid open, to show the petals and the insertion of the stamens; 4, a transverse section of a fruit exhibiting the parietal placentation; 5, a longitudinal section of a seed, with the minute embryo at the end of the albumen.

5-parted, regular, coloured, imbricated, or somewhat valvate in æstivation; petals 5, minute, inserted in the throat of the calyx; stamens 5, inserted alternately with the petals, very short; ovary 1-celled, with 2 opposite parietal placentæ; ovules numerous, on short stalks, anatropal, style 2- 3- or 4-cleft. Berry crowned with the remains of the flower, 1-celled, the cell filled with pulp; seeds numerous, suspended among the pulp by long filiform cords; testa externally gelatinous, adhering firmly to the albumen, which is horny; embryo minute, with the radicle next the hilum.

Nothwithstanding the great dissimilarity in the appearance of these plants and Indian Figs, the two orders were formerly confounded, and are still accounted by many writers conterminous, chiefly on account of their both having inferior pulpy fruit and parietal placentæ. They are natives of the mountains, hills, and woods and thickets of the temperate parts of Europe, Asia, and America, but unknown in Africa. In North America they are particularly abundant, and on the mountains of Northern India they contribute to give a European character to that remarkable region. In the tropics of Asia and the South Sea Islands they occur in the form of *Polyosma*, a genus which derives its name from the excessive fragrance of its flowers.

To this order belongs the genus *Ribes*, of which the Gooseberry and Currant are different species. The Black Currant is tonic and stimulant, and has fragrant glands upon its leaves and flowers. [RIBES.]

GROSSULARITE. [GARNET.]

GROUND-HOG. [AARD-VARK.]

GROUND-IVY. [NEPETA.]

GROUNDLING. [COBITIS.]

GROUNDSEL. This commonest of annual weeds is the plant called *Senecio vulgaris* by botanists, which was originally a native of Europe and the north of Asia, but which has followed the steps of man in his progress of colonisation till it has established itself in almost every place where there is a European settlement. It forms one species in the largest genus of plants yet known, no fewer than five hundred and ninety-five others being distinguished by M. De Candolle in his 'Prodromus.' Although in the eyes of man a worthless weed, Groundsel contributes largely to the support of small birds, which feed upon its fruit, or seeds as they are commonly but incorrectly called. [SENECIO.]

GROUSE. [TETRAONIDÆ.]

GROUSE, RUFFED. [BONASIA.]

GRUB, a name applied to the chrysalis or pupa state of insects; it is also sometimes applied to the larva state. [PUPA.]

GRUIDÆ, a family of Birds, including those known by the name of Cranes, and closely allied to the *Ardeidæ*, a family embracing the Spoon-Bills, Herons, Bitterns, and Storks.

Willughby thus generally defines his section of Cloven-Footed Piscivorous Water-Fowl:—"These have very long necks; their bills also are long, strong, ending in a sharp point to strike fish, and fetch them from under stones or brinks: long legs to wade in rivers and pools of water: very long toes, especially the hind toe, to stand more firmly in rivers; large crooked talons, and the middle serrate on the inside, to hold eels and other slippery fishes the faster, or because they sit on trees. Lean and carrion bodies, because of their great fear and watchfulness." He makes the section to consist of the Herons, Bitterns, &c., Storks, "the *Ibis* of Bellonius" (Belon), and the Spoon-Bills.

Ray places at the head of the *Aves Aquaticæ*, the "*Fissipedes*" (Cloven-Footed), "quæ circa aquas versantur, iis tamen non innatant" (which haunt the waters, but do not swim in them). The first section of these, consisting of the "Maximæ, singulares et sui generis," contains the Cranes (*Grus*, including the *G. Indica* and *G. Balearica*, the *Jabirus*, the *Çariama*, and the *Anhima*). Then come the "Aves aquaticæ, fissipedes, piscivoræ, ranivoræ, et serpentivoræ," the Storks and the *Ibis nigra*. Next to these are arranged the *Ardearum* genus (Herons and Bitterns), and then the *Ardeæ Exoticæ*, including the Soco, &c., and the Spoon-Bills.

The Stork, the Heron, the Spoon-Bill, &c., with a heterogeneous crowd of other birds, are brought under Brisson's 17th order.

The genus *Ardea*, in the 12th edition of the 'Systema Naturæ,' embraces the Herons, the Bitterns, and the Cranes (including the Balearic Crane and the Demoiselle, *Anthropoides*); the Jabiru, Boat-Bill, and Spoon-Bill are generically distinguished under the names of *Mycteria*, *Cancroma*, and *Platalea*. They form part of Linné's 4th order, *Grallæ*.

Dr. Latham's 7th order, *Grallæ*, embraces the *Ardeidæ* and *Gruidæ* among the rest of the Wading Birds.

The same families are scattered through M. Lacépède's Oiseaux de Rivage (*Grallatores*).

M. Duméril's 5th order of birds, Échassiers (Waders), contains his 16th, 17th, 18th, and 19th families. The Oyster-Catcher is included in the 16th (*Pressirostres*, or Ramphostènes); the Open-Beak, Bec-Ouvert (*Anastomus* of Illiger), the Heron, the Stork, the Crane, the Jabiru, and *Ibis* (*Tantalus*), form the 17th family, the *Cultirostres*, or *Ramphocopes*. The Spoon-Bill and Boat-Bill belong to his 18th family, the *Latirostres*, or *Ramphoplates*.

Among the *Grallatores* of Illiger the *Herodii* contain the genera *Grus*, *Ciconia*, *Ardea*, *Eurypyga*, *Scopus*, *Cancroma*, and *Anastomus*. The genera *Tantalus* and *Ibis* form the *Falcati*, and *Platalea* is placed among the *Hygrobatæ*.

Cuvier's Échassiers comprehend the *Brevipennes*, the *Pressirostres*, the *Cultirostres*, the *Longirostres*, and the *Macrodactyles*.

The *Cultirostres* consist of the Cranes, the Boat-Bills, the Herons, the Storks, the *Jabirus*, the Ombrettes, the Open-Beaks, the *Tantali*, and the Spoon-Bills.

M. Vieillot's Échassiers are divided into two tribes: the 1st, the Di-tridactylous; the 2nd, the Tetradactylous. The 6th family of these Waders (*Latirostres*) consists of the Spoon-Bills and Boat-Bills; the 7th (Herodions) comprehends the Ombrette, the Open-Beak, the Herons, the Storks, the *Jabirus*, &c.; and the 8th (*Ærophones*), the Cranes (*Grus* and *Anthropoides*).

The *Ardeidæ* and *Gruidæ* are placed by M. Temminck under his 2nd family of *Gralles* (Waders).

In M. De Blainville's method the *Ardeidæ* and *Gruidæ* are comprehended under the Cicouiens, his 3rd family of *Grallatores*, and in the same method as further developed by M. Lherminier, the 23rd family (first sub-class, or Normal Birds) consists of the Cranes (*Grus* of Pallas); and the 24th family (same sub-class) of the *Herodii* of Illiger.

Mr. Vigors considers that the *Grallatores* are naturally divided into these five families:—*Gruidæ*, *Ardeidæ*, *Scolopacidæ*, *Rallidæ*, *Charadriadæ*; and he places the *Ardeidæ* in the normal group and the *Gruidæ* in the aberrant group. He remarks that the species that enter into the family of *Gruidæ*, most of which were comprised originally in the genus *Ardea* of Linnæus, are separated from the remainder of that group by their food, which is chiefly vegetable; by their manners, which approach nearer to those of the land-birds; and by the formation of their bills and feet, the former of which are more obtuse at the end, and the latter shorter than is observable in the true *Ardeæ*. In these characters, Mr. Vigors observes, as well as in their general appearance, more particularly with respect to their plumage, they have a near alliance with the *Struthionidæ*. *Psophia* [AGAMI] of Linnæus is the first genus of this family to which Mr. Vigors calls our attention. This genus, in the comparative shortness of the bill, is considered by Mr. Vigors to be connected with the *Anthropoides* of M. Vieillot, the Numidian Demoiselle; while he regards the Crowned Crane of Africa (the Balearic Crane of authors, *Ardea pavonina* of Linnæus) as uniting this genus to the true *Grus* of the present day. "If the genus *Dicholophus* of M. Illiger," continues Mr. Vigors, "be found to belong to the Wading Birds, of which I have little doubt, its situation will most probably be in the present family, to which it bears a nearer resemblance in plumage and general structure than to any other division of the order. In this case it will form a more immediate link than any group at present known in the family with the *Charadriadæ*, which meet it at the corresponding extreme of the order; its shorter and more elevated hind toe forming the passage between the fully tetradactyle foot of the *Gruidæ* and the tridactyle foot of the *Charadriadæ*." We have seen [ÇARIAMA] that the habits of *Dicholophus* are not those of the Wading Birds, although in the whole of the visceral arrangement a close affinity may be observed to the *Gruidæ*.

Mr. Vigors remarks further that Cuvier has noticed the union that takes place between the last groups alluded to by Mr. Vigors and those of the *Ardeidæ* by means of the genera *Aramus* of Vieillot and *Eurypyga* of Illiger. These, he observes, lead to the extensive assemblage of species contained under *Ardea* (Linn.) and *Ciconia* (Briss.), both of which groups are connected by their general form and habits, but differ by some minute yet strongly-marked generic distinctions. Intermediate between *Ardea* and *Ciconia* appear those forms which display so remarkable a dilatation of the bill, namely, *Cancroma*, *Phœnicopterus*, and *Platalea* of Linnæus. The two last of these groups, continues Mr. Vigors, are equally distinguished by a greater development of the membrane that connects the toes than is observable in the other Waders, which join them on each side; and in one of them, the *Phœnicopterus*, this character, he remarks, is carried so far to the extreme as to have occasioned some systematists to place the birds of that genus among the *Natatores*. [DUCKS.] "But," says Mr. Vigors in conclusion, "the whole of the family have a membrane more or less extensive at the base of the toes; and if we compare the feet of the common *Ciconia alba*, of the *Platalea*, and the *Phœnicopterus* together, we shall see a gradual increase of this membrane in extent until it reaches the extreme in the latter genus. Among the groups that are allied to *Ciconia* there are many that resemble it in general character, but deviate from it in the form of the bill. Among these we may particularise *Scopus* (Linn.), distinguished by its more compressed and furrowed mandibles; the *Mycteria* (Linn.), where the point of the bill turns upwards; and the *Anastomus* (Ill.), where the mandibles, united at the base and at the point, leave an open space in the centre. The genus *Tantalus* (Linn.) bears an evident affinity to the same group, and has consequently been united to it in the arrangement of every systematic naturalist. It differs chiefly by the downward curvature of the bill. To this genus may be united the *Ibis* of M. Lacépède, which, in its more slender bill, bears an affinity to *Eurypyga*, from whence we commenced our inquiries into the family." The same author unites the *Scolopacidæ* with the *Ardeidæ* by means of *Numenius* of Brisson, as approaching *Ibis* most closely in its bill.

Prince Bonaparte makes the *Herodii* the 3rd family of the order *Grallæ*, and includes under it the genera *Grus*, *Ciconia*, *Ardea*, and *Aramus*: his 4th family (*Falcati*) consists of the genera *Tantalus* and *Ibis*. ('Specchio Comparativo.')

Mr. Swainson ('Natural History and Classification of Birds,' vol. ii.) is of opinion that the *Ardeadæ*, or Herons, by means of the Cranes, show the strongest affinity to the Ostriches, and thus unite the rasorial with the wading order. "Nearly all the Cranes," writes Mr. Swainson, "are large birds, with short and powerless wings, long and frequently naked necks, and more terrestrial in their habits than any of their congeners. The beautiful genus *Phosphia* (*Psophia?*), if truly belonging to this family, is more of a gallinaceous than a wading bird." After referring to the genus *Anthropoides*, Mr. Swainson thus continues:—"The more typical cranes (*Grus*, Pallas) are large birds, few indeed in species, but dispersed over Europe, America, and Asia: they seem to prefer the seclusion and security of marshes, and feed both upon seeds, herbage, worms, and small reptiles. The *Ardeadæ*, or Typical Herons, differ from the last in being composed of birds decidedly carnivorous; they are known by a larger and more pointed bill, and by the superior length of the legs. The herons, as a whole, are the most beautiful of all the waders, not so much from the colours of their plumage as from the elegant crests and prolonged feathers which ornament nearly all the species. They build in societies, but generally feed and live solitary. Like the kingfishers and many of the fissirostral birds, the greater part watch for their prey from a fixed station: a sheltered nook by the side of a river, or a projecting rock by the sea-side, over deep water, frequently serves them as a convenient post; here they watch for passing fish, which they dexterously spear or transfix by their long and sharp bill. Some of these birds are of a gigantic size; others are very small, but have all a very long neck, covered more or less by strong and loose feathers. The Tiger-Bitterns (*Tigrisoma*, Swainson) are exclusively found in South America, but the true bitterns seem restricted to no particular climate. The Boat-Bills (*Cancroma*, Linnæus) differ most essentially from the herons, since they have a short and very broad bill, shaped something like a boat with its keel uppermost." [Boat-Bill.] . . "The Spoon-Bills (*Platalea*) show a different but a no less singular form of beak, from which their name has been derived. The Storks (*Ciconia*) are among the largest of the heron family, one species (*Ciconia gigantea*) measuring, when standing erect, near 5½ feet; they are social and useful birds, and from destroying vast numbers of reptiles and other vermin are encouraged in many countries to build on the habitations of man. The chin and eyes are bare of feathers, but in *Mycteria*, which possibly enters into this family, the greatest part of the head and neck is entirely bare: one species inhabits America, one Asia, and one Australia. The tufted umbre forms the African genus *Scopus*, and is the only species known; the plumage is particularly soft, and the back of the head furnished with a lax tuft of feathers: this is obviously allied to the Open-Bills (*Anastomus*, Ill.), a singular form, remarkable for a thick and very powerful bill gaping in the middle. . . These are the principal genera which appear to enter this family, of which the herons and cranes form the two most typical groups."

In the 'Synopsis' (same volume), Mr. Swainson places the *Ardeadæ* as the first family of the *Grallatores*, or Waders, with the following definition:—"Size large; bill long, conic, very hard, straight, and compressed; hind toe moderate, and placed on the same level as the thers." The family, according to this author, includes the following genera and sub-genera:—*Ardea*=*Ardea*, *Egretta*, *Butor* (Bitterns), *Tigrisoma* (Tiger-Bitterns), *Nyctiardea*, Swainson (Night-Herons); *Cancroma*; *Platalea*; *Ciconia* (including *Mycteria* as a sub-genus); *Hæmatopus*; and *Scopus*.

Species of the families *Gruidæ* and *Ardeidæ* are to be found in all the four quarters of the globe. They seldom occur in the very cold regions.

We now proceed to give the characters of the genera of *Gruidæ*:—

Grus (Pallas).—Bill of the length of the head or rather longer, strong, straight, compressed, the point in the form of an elongated cone, obtuse towards the end; lateral base of the mandible deeply channelled; base of the bill elevated. Nostrils in the middle of the bill, pierced through and through in the groove, and closed backwards by a membrane. Region of the eyes and base of the bill often naked, or covered with warty excrescences (mamelons). Feet long and strong, a large naked space above the knee; three anterior toes, the middle one united to the external by a rudiment of a membrane, interior toe divided, posterior toe articulated higher on the tarsus. Wings moderate; first quill shorter than the second, which last is nearly as long as the third, and that is the longest; secondaries nearest to the body, arched, or very long and subulate in some foreign species.

Bill of Common Crane (*Grus cinerea*).

In the greater part of the species the trachea of the male forms circumvolutions upon itself; in the other similar sinuosities occur in both sexes, which do not differ in external appearance. Moult once in the year. (Temminck.)

Grus cinerea. The general plumage is ashy gray; throat, front of the neck, and occiput, very deep blackish gray. Forehead and space between the eyes and bill furnished with black hairs; top of the head naked and red. Some of the secondaries arched, longer, and loose-barbed. Bill greenish-black, horn-coloured towards the point, and reddish at the base; iris red-brown. Feet black. Length from the bill to the end of the tail 3 feet 8 or 10 inches. The old birds have a large whitish space behind the eyes and along the lateral part of the upper portion of the neck.

Common Crane (*Grus cinerea*).

Young Birds before their second autumnal moult.—No nakedness on the top of the head, or the space hardly visible. The blackish ash-colour of the front of the neck and occiput non-existent, or only indicated by longitudinal spots.

This is the Γέρανος of the Greeks; *Grus* of the Romans; Grue and Grua of the Italians; Grue of the French; Grulla of the Spanish; Kranich and Aschgrauer Kranich of the Germans; Trane of the Danes; Goran of the Welsh; and Crane and Common Crane of the English.

The habits of the Crane are migratory and gregarious. Mr. Selby remarks that in its contour and gait it bears a considerable resemblance to some of the *Struthionidæ*, and that we are reminded of the ostrich by the long flowing plumes that overhang the tail. He is of opinion that through this and other families its affinity to the Rasorial Birds is readily traced; and he observes that in its internal conformation it differs very essentially from the more typical familes of the *Grallatores*, and that its strong and muscular stomach indicates a different general economy from that of the *Ardeidæ*. This is quite true; but whilst the Crane frequents open and cultivated lands for the sake of newly sown corn and seeds to be found in such tracts, it is far from averse to small testaceous mollusks, worms, frogs, and other reptiles. Temminck says that the nest is placed among the rushes, &c., and sometimes on the walls of isolated houses. The pale bluish-green eggs, marked with brown, are two in number.

Temminck states that this crane inhabits the marshy plains of the Oriental countries; that it is common in the north, migrates regularly in spring and autumn, is rare in its passage in Holland, and only in very severe winters. Asia is one of the tracts of country much frequented by it. Dr. Von Siebold notices it in his list of birds killed at Japan. Mr. Selby states that its equatorial migrations extend to India, Egypt, and other warm parts of Asia and Africa, but that it retires in summer to the northern and eastern parts of Europe to breed. The migrations are performed high in the air, and the progress of the flock may be traced by the loud cries of the birds when they are beyond the reach of sight. The nighttime is frequently chosen for these changes of locality. Prince Bonaparte notes it as very rare and accidental near Rome; Willughby however saw many of them in the poulterers' shops in winter. But it is in England that the alteration of the country by drainage and enclosure has caused perhaps the most remarkable absence of these fine birds. They were numerous in the time of our ancestors, and highly esteemed by them, both as objects of sport and as furnishing a dish fit for the table of princes. By 25 Henry VIII., c. 11, confirmed by 3 and 4 Edw. VI., c. 7, twenty pence was the forfeiture for each egg of the Crane taken and destroyed. Willughby says, "They come often to us in England;

and in the fen countries in Lincolnshire and Cambridgeshire there are great flocks of them; but whether or no they breed in England (as Aldrovandus writes he was told by a certain Englishman, who said he had often seen their young ones), I cannot certainly determine, either from my own knowledge or from the relation of any credible person." In Pennant's time he had come to the conclusion that the Cranes had forsaken our island. "A single bird," says he, "was killed near Cambridge about three years ago, and is the only instance I ever knew of the crane being seen in this island in our time." Dr. Latham mentions only four instances as occurring within his memory of the Crane having been met with in England. (Pennant, 'Brit. Zool.,' 1812.) Montagu and Dr. Fleming mention a small flock that visited Zetland in 1807, and Mr. Selby received information of one killed in Oxfordshire in December 1830. The Crane can now be only regarded as an accidental and rare visitant to our islands.

"The flesh is very savoury and well tasted, not to say delicate" (Willughby), and indeed it seems to have been highly prized in former days. At the intronazation of George Nevell, the archbishop above alluded to, 204 cranes were served, and in the Northumberland Household-Book the price of the Crane (Cranys) is marked sixteen pence. At the marriage-feasts also above mentioned, one of the items in the first is "9 Cranes, every Crane three shillings and four pence;" and in the second we find "Item for a Standert, Cranes 2 of a dish" for the second course; and in the expenses we find "Item, in Cranes 9 . . . 0*l.* 30*s.* 0*d.*" The long drooping feathers are valuable as plumes.

Anthropoides (Vieillot).—Mr. Bennett remarks ('Gardens and Menagerie of the Zoological Society') that the name of *Anthropoides,* conferred upon this genus by its founder, M. Vieillot, owes its origin to a mistaken reading of a passage in Athenæus, which the French academicians of the 17th century improperly applied to the Demoiselle, or Numidian Crane, regarding the resemblance to man implied by the term *Anthropoides* as a convincing proof that the *Otus* of the Greeks was a synonym of the bird, which they were themselves describing under the name of Demoiselle, from its elegant attitudes. "It is difficult however," says Mr. Bennett, "to conceive how these learned men, with M. Perrault at their head, could have stumbled on so gross a misapprehension; for the passages cited by them from the Greek and Roman authors prove beyond all question that the *Scops* and *Otus* of the former and the *Asio* of the latter were in truth nothing else than owls, and had consequently no connection with the Numidian Crane. M. Savigny, on the other hand, refers the latter bird to the *Crex* of Aristotle and other classical authors; but we must confess that we entertain considerable doubt of this opinion also. The scattered notices of the ancient *Crex* appear to us by far too scanty and indefinite to admit of their positive appropriation; and they combine moreover several traits which are quite irreconcileable with the identity of the two animals. With the exception of this distinguished naturalist, almost all the modern authors who have spoken of the Demoiselle have merely copied Buffon, who with singular inconsistency, at the same time that he corrects the error of synonymy into which the academicians had fallen, adopts all their quotations founded upon this very mistake. The truth is, that the real history of the bird cannot be traced with certainty beyond the period of M. Perrault's memoirs, in which it was for the first time described under the fanciful denomination which it has since attained." We have given this passage entire because the exemplary and industrious zoologist who penned it is, in our opinion, borne out in his observations, and because it conveys a good lesson of the danger of hastily appropriating Greek or Roman names to existing animals. Such an appropriation should never be made without the clearest evidence of the identity of the species. But however right Mr. Bennett may be, the term *Anthropoides* is now generally received by ornithologists as the generic appellation for certain species of cranes, and must be retained, the only question being what species should be arranged under it. The Demoiselle and the Balearic Crane were the only two species of *Anthropoides* (Vieillot), till a third and most elegant species, *Anthropoides Stanleyanus* (Vigors), *Anthropoides Paradisæus* (Bechstein), was added. Mr. Vigors would include the whole of these three species in the genus; but Mr. Bennett remarks that the discovery of that species, closely allied as it is to the Demoiselle, seems to determine the existence of that form as a distinct type, and to render it more necessary to isolate the Crowned or Balearic Crane (*Balearica pavonina, Ardea pavonina,* Linn.), under another generic name, *Balearica* (Brisson).

A. Virgo, Ardea Virgo of Linnæus, the Demoiselle, is about 3 feet 6 inches high measured to the top of the head: from the point of the bill to the tip of the tail it is about 3 feet in length. Upper part of the head light gray; sides of the head, neck, and depending breast-feathers, blackish; head and neck fully feathered. A tuft of pure white loose-barbed feathers, three or four inches long, directed backwards with a curvature downwards behind each eye. General tint slaty-gray; outer portions of all the quill-feathers dingy-black. Secondaries longer than the primaries, forming when the wings are folded dependent downward-curved plumes. Bill yellowish or flesh-coloured; iris reddish-brown.

The habits of the Demoiselle are migratory, and its food consists in great measure of grain and seeds, though it occasionally takes small fishes, mollusks, and insects. Gizzard muscular. The Demoiselle produced young in the menagerie at Versailles, and one which was hatched and bred there lived twenty-four years.

Demoiselle (*Anthropoides Virgo*).

Africa is the head-quarters of this bird. It has been observed in the north, along the Mediterranean, the west from Egypt to Guinea, in the interior, and in the south near the Cape of Good Hope. It has been killed in Nepaul, according to Mr. Gould; is found on the southern coasts of the Black Sea and Caspian, and has been observed at Lake Baikal. It is occasionally seen in Europe, and appears about Constantinople in October. At the inundation of the Nile great numbers arrive in Egypt.

A. Stanleyanus (so named by Mr. Vigors in honour of the late Earl of Derby, then Lord Stanley, President of the Zoological Society of London), *A. Paradisæus* of Bechstein, the Stanley Crane, is in its general plumage bluish-gray, the top of the tumid head, which is well covered with soft feathers, is whitish, and there is a brownish post-

Stanley Crane (*Anthropoides Paradisæus*, Bechstein).

ocular band; the irides are chestnut-black, and the points of the quills, tail, &c., are brownish-black. Length from the tip of the bill to the end of the tail 3 feet 6 inches. Mr. Vigors mentions particularly the greater length and development of the hallux in this species, in which character, he observes, the bird seems to be intermediate between *A. Virgo* and the more typical *Gruidæ.* He considers the

Balearic Crane as according with this species in this particular, and by the additional character of the naked cheeks and caruncle under the chin, as exhibiting a still nearer approach to the true *Grus*. *A. Virgo*, on the other hand, by the slight development of the hallux, appears to him to possess the nearest affinity of all the birds in the group to the *Charadriadæ*.

"In manners and gestures," says Mr. Vigors, "the *Anthropoides Stanleyanus* appears to conform most intimately with the Demoiselle, displaying the same delicacy and elegance of attitude, and the same majesty, together with the same graceful playfulness in all its movements. I once had the good fortune to see it when released from the place of its confinement and set at liberty into an adjoining yard; and it was scarcely possible to witness a scene of more grace and animation. The bird, when after a few movements it felt itself free, bounded into the air, and traversed the yard with singular velocity, and a peculiarity of motion which could neither be termed running nor flying: with its wings expanded, and its long quill-feathers streaming just above the ground, it sailed and swept along the open space without regard to the numerous spectators who watched its movements, luxuriating in all the buoyancy and excursiveness of new-felt liberty. I understand that it is particularly eager in its pursuit after insects, which it takes when they are upon the wing; and that they seem to be its natural and most acceptable food. We may readily conceive what myriads of winged creatures it would encircle within its wings as it swept along its native marshes, in the manner observed above, and which it would thus bring within the compass of its prey." ('Zool. Journ.,' vol. ii.)

This beautiful bird is an inhabitant of the East Indies.

A. pavoninus, Vieillot (*Balearica pavonina*, Brisson; *Ardea pavonina* of Linnæus), the Balearic or Crowned Crane, received its English and French common name from its being supposed to be the Balearic Crane of the ancients. Its height when full grown is about 4 feet. We select Mr. Bennett's description: "Its plumage is of a bluish-slate colour on the neck and on both surfaces of the body; the quill-feathers of the tail and the primaries of the wings are of a beautiful black; the secondaries, which extend beyond the base of the tail, of a bright and glossy-brown; and the wing-coverts pure white. The cheeks and temples are entirely naked, and are coloured of a bright rosy-red, which sometimes overspreads the whole of the naked surface, and sometimes is confined to a portion of it, the remainder in this latter case becoming perfectly colourless and of a dull white. Beneath the upper part of the throat a similar naked space is gradually developed, which terminates in a dependent fold of the skin, like the wattle of a turkey, but more uniform on its surface, and of a brilliant red. As this prolongation is not always met wit, it has been

Crowned Crane (*Anthropoides pavoninus*).

considered by some writers as a mark of sex; but of the two birds examined by the French academicians, the one possessed it and the other not, and yet both were females; it may therefore with greater probability be considered as the result of age. The fore part of the head is covered by a close tuft of short, smooth, even, velvety feathers of a deep black; and behind these rises a very remarkable crest, consisting of a large number of flat yellowish filaments, each twisted spirally on itself, fringed along its edges with a series of black-pointed hairs, and terminating in a blackish pencil. These filaments are of nearly uniform length, and measure 4 or 5 inches from base to tip. They take their origin from a roundish space on the back of the head, and expand equally at their extremities into a circle of considerably larger diameter than the head itself. The bill, legs, and feet are of a dusky-black; and the iris is remarkable for being almost destitute of colour. As in most of the birds of this family, the feathers of the lower part of the neck are long, narrow, and gracefully dependent over the breast."

This description is so good in the main that we have given it in the author's own words; but his observations with regard to the wattle require confirmation. Indeed, he himself, as secretary to the Zoological Society, subsequently brought under the notice of a meeting of its members, specimens from the Society's museum, of Crowned Cranes from Northern and from Southern Africa, with the view of illustrating the characters which distinguish as species the birds from those several localities. Their specific distinction, he stated, on the authority of Professor Lichtenstein, had been pointed out, nearly 30 years from that time, by the professor's father, who gave to the Cape bird the name of *Grus Regulorum*. This distinction had not however, Mr. Bennett remarks, been generally known among ornithologists, although to those connected with the Society it had for some time been familiar, from observation both of numerous skins and of living individuals. In the bird of North Africa, for which the specific name of *Pavoninus* will be retained, the wattle is small, and there is much red occupying the lower two-thirds of the naked cheeks: in that of South Africa the wattle is large, and the cheeks are white, except in a small space at their upper part; the neck also is of a much paler slate-colour than that of the North African species. Mr. Bennett added that the latter characters had been observed to be permanent in an individual presented to the Society in April 1829, from the collection of the late Marchioness of Londonderry, then still living at the Gardens. They existed also in both the individuals presented by Sir Lowry Cole.

Dr. J. E. Gray remarks, that the oval form of the nostrils in the Crowned Cranes, added to other distinguishing characters which had frequently been pointed out, might be regarded as indicating a generic difference between them and the Demoiselle and Stanley Cranes, in which the nostrils have the lengthened form usual in the genus *Grus*, a genus from which they scarcely differ, except in the comparative shortness of their bill. For the group including the Crowned Cranes the name of *Balearica* might, he thought, be retained, and that of *Anthropoides* be appropriated to the one comprehending *Anthropoides Virgo*, Vieill., and *A. Paradisæus*, Bechst. ('Zool. Proc.')

The species with the small wattle and other differences will, according to this proposition, stand as *Balearica pavonina*. It is a native of Northern and Western Africa.

The species with the large wattle, &c., will stand as *Balearica Regulorum*. It is found in Southern Africa.

These birds are presumed to be migratory; but little is known of them, except in captivity, to which the birds are easily reconciled, living in friendship with the domestic poultry, and other captives, and even, as we have heard, interfering to prevent disputes. In a state of nature they are said to frequent swampy places, and to subsist partly upon fishes, worms, and insects, and partly on vegetable substances. They run with the wings expanded, and with great rapidity. Their note is loud, trumpet-like, and hoarse. In the catalogue of the African Museum, one of the species, there called the Kaffir Crane, is said to be held sacred by the Kaffirs bordering upon the Cape Colony; and if one should happen to be killed, even by accident, a calf or young cow must be slaughtered as an atonement. Mr. Swainson ('Classification of Birds') notices specimens of *Ardea pavonina*, Linn., as having been brought to him when in Malta, from the little island of Lampidosa, where, he says, they are by no means scarce.

Our English readers will find most of the birds above described living in the Gardens of the Zoological Society in the Regent's Park, together with many others of this very fine family of birds.

The bird called the Adjutant Crane, belongs to the family *Ardeidæ*. It is the *Ciconia Argala* of naturalists. [CICONIA.]

GRUINA'LES, a name given by Linnæus to the natural order of Plants now called *Geraniaceæ*.

GRUMIXAMEIRA, a Plant belonging to the natural order *Myrtaceæ*, yields a fruit which is spoken of by Martius as excellent eating.

GRY'LLIDÆ (*Achetidæ*, Leach), a family of Insects belonging to the order *Neuroptera*. Distinguishing characters:—Thighs of posterior legs large; tibiæ armed with spines; abdomen terminated by two long and slender fleshy appendages; tarsi of the anterior and intermediate pairs of legs 3-jointed; antennæ usually long and cetaceous.

The three principal genera contained in this family are *Gryllus*, *Gryllotalpa*, and *Tridactylus*. In the genus *Gryllus* the anterior tarsi are simple; the labial palpi are short; the anal appendages are long and slender, thickest at the base and pointed at the apex; the elytra in the females are studded with minute nervures which cross each other in an oblique manner; in the males the nervures are less numerous and irregularly disposed; the wings are longer than the elytra, and when not in use are folded longitudinally; the females are furnished with a long ovipositor.

Gryllus domesticus (Linn.), the Common House-Cricket, affords an example of this genus. This insect is about three-quarters of an inch in length, and of a pale-brown colour, with blackish markings on the head and thorax. It is found throughout Europe; frequents houses, and prefers the vicinity of the fire. The male makes a shrill noise, which is caused by the friction of the elytra against each other. These insects are of nocturnal habits, take to the wing readily, and can leap a considerable distance. The wingless specimens are the larvæ, and those which have only rudimentary wings are the pupæ.

There is another species which is tolerably common in some parts of England and in various parts of the continent—the Field-Cricket, or Grasshopper (*G. campestris*, Linn.). This insect is of a larger size than the house-cricket, and of a black colour; the inner side of the hinder thighs is red, and the elytra are brown, with a yellowish band at the base. The field-cricket generally frequents dry sandy districts; it burrows in the ground and preys upon other insects. The female is said to lay about 300 eggs. *G. viridissimus* is the Common great Green Grasshopper. [LOCUSTA.]

The species of the genus *Gryllotalpa* are remarkable for the large size of the anterior pair of legs and their fitness for burrowing; these legs are very broad, and flattened, notched beneath at the extremity, and bear a great resemblance to the fore feet of the mole—hence the name of Mole-Cricket has been applied to them.

Gryllotalpa vulgaris (Lat.), the Mole-Cricket, is common in some parts of England, but appears to confine itself to particular districts. It is upwards of 2 inches in length and of a brown colour; the legs are yellowish. This insect excavates subterranean galleries of considerable extent, and in so doing throws up small mounds of earth, after the manner of its prototype, among the *Mammalia*. It is said to do much mischief in gardens and plantations by injuring the roots of plants. As yet it is doubtful whether these insects prey upon worms or other insects, or whether they feed upon roots. Latreille supposes the former to be the case. We understand that the Duke of Devonshire's grounds at Chiswick are much infested by this insect.

In *Tridactylus* the antennæ are short and 10-jointed; the tarsi are 3-jointed; the females have no distinct ovipositor, but the apex of the abdomen is furnished with four small appendages, of which the two upper are 2-jointed. In lieu of tarsi to the posterior legs there are some small moveable hooked appendages (three in the typical species); the elytra are shorter than the abdomen, and of a triangular form; the wings exceed the elytra in length.

The small insects belonging to this genus are highly interesting, not only on account of their peculiar structure, but also in their habits. The species as yet discovered are very limited in number, and have been found only in the south of Europe and in North Africa; they invariably live near the margins of rivers, lakes, or other pieces of water, and it appears essential that the soil should be damp and consist of fine sand. In this sand they burrow, first vertically to the depth of a few inches, and then they form numerous small horizontal galleries. In the construction of these galleries they are probably in search of food. Sand is eaten and voided by these insects, and it is supposed that they receive their nutriment from the minute animalculæ left in the sand by the retiring water. For a detailed account of the habits of these insects see 'Histoire Naturelle des Insectes,' by Messrs. Audouin and Brullé, tom ix. p. 192.

The genus *Repipteryx* of Mr. Newman ('Entomological Magazine,' vol. ii. p. 204) is closely allied to the last-mentioned insects. The species upon which that entomologist founded the genus is from Para in South America.

In the family *Gryllidæ* are also included the genera *Æcanthus*, *Phalangopis*, *Platydactylus*, *Sphærium*, and *Cylindrodes*. The species upon which the last mentioned genus is founded is figured in Griffith's Cuvier's 'Animal Kingdom—Insects,' vol. ii. pl. 131. It is remarkable for its slender and cylindrical form, but in many respects approaches the genus *Gryllotalpa*.

GRYLLOTALPA. [GRYLLIDÆ.]

GRYLLUS. [GRYLLIDÆ.]

GRYPHÆA, a genus of *Conchifera monomyaria* (Lam.) closely allied to the oyster, and very abundant in the secondary strata of Europe from the Lias upwards to the Chalk, but scarcely known in tertiary strata. [OSTRACEA.]

GRYS-BOC. [ANTILOPEÆ.]

GUACHA'RO BIRD (*Steatornis*, Humboldt; *Podargus*, Cuv., Temm.), a Bird which has been confounded with *Podargus*, but which, according to the account of its food and habits by Humboldt, and to the opinion of some ornithologists, may be considered a genus distinct from the true *Podargi*. It has the following generic characters:—Bill hard, horny, much wider than it is high, nearly equalling the head in length; upper mandible strongly bent downwards into a rather sharp hook, and armed near its middle with two small teeth. Nostrils linear, longitudinal, nearly closed by a plate placed half-way down the mandible; lower mandible rather slender, dilated at its base; gape considerable, and extending to the posterior part of the eye; base of the bill furnished with stiff hairs directed forwards. Feet short, weak, with four toes separated up to their base; claws arched and weak, not dentilated. Fourth quill longest. (Humboldt.)

Steatornis Caripensis, (Humb.), the Guacharo Bird, is the type of the genus. It is the size of a common fowl; plumage sombre, brownish-gray, mixed with small striæ and black dots; large white heart-shaped spots bordered with black on the plumage of the head and on the wing- and tail-feathers. The plumage of the back is without spots. Tail wedge-shaped.

Guacharo Bird (*Steatornis Caripensis*).

Baron Alexander de Humboldt, in his 'Personal Narrative,' gives a lively description of the locality and habits of this remarkable and useful bird, and we shall endeavour to select the chief points of his account.

The cueva, or cavern, of the Guacharo, and the coolness of the climate, give celebrity to the valley of Caripe. The people love the marvellous, and are never tired of discussing the subject of a cavern that gives birth to a river and is haunted by thousands of nocturnal birds, whose fat is employed in the Missiones for culinary purposes. The traveller on his arrival at Cumauá soon hears of the stone of Araya for the eyes—of the labourer of Arenas who gave suck to his infant—and of the cavern of Guacharo, said to be several leagues in length—even to weariness. The cavern, called by the natives 'a mine of fat,' is not situated actually in the valley of Caripe, but at the distance of three short leagues from the convent, towards the west-south-west, and it opens into a lateral valley terminated by the Sierra del Guacharo. Humboldt and his party, accompanied by the alcaids, or Indian magistrates, and the greater part of the monks of the convent, set out for the Sierra on the 18th of September; and they at first traversed for an hour and a half a narrow path towards the south, across a plain covered with beautiful turf. They then turned westward, tracing up a small river which issues from the cavern. The ascent continued for three-quarters of an hour, during which they went sometimes in the shallow water and sometimes between the torrent and a rocky wall, on a very miry and slippery soil. This part of the road, with its incumbrances of falling earth, scattered trunks of trees, over which the mules could hardly pass, and a profusion of creeping plants that covered the ground, was very fatiguing. When they arrived at the foot of the lofty mountain of Guacharo they were only 400 paces from the cavern, without yet perceiving the entrance. The torrent runs in a hollow excavated by the waters: and they went on under a ledge, or cornice, the projection of which prevented them from seeing the sky. The path winds like the river, and at the last turning they suddenly stood before the immense opening of the cave. Humboldt, who had already been familiar with caverns, confesses that the reality far exceeded his expectations.

The Cueva del Guacharo is pierced in the vertical profile of a rock, and the entrance is towards the south, forming a vault 80 feet broad and 72 feet high—an elevation but a fifth less than that of the Louvre. The rock surmounting the cavern was covered with trees of gigantic height, and all the luxuriant profusion of an intertropical vegetation. Our space prevents an enumeration of the beautiful and curious plants, among which the *Orchidaceæ* are not forgotten, recorded by the Baron, and dwelt on by him with a pardonable rapture; but it is worthy of observation, that this luxuriance penetrated even into the vestibule of the cave. The travellers saw with astonishment plaintain-leaved Heliconias 18 feet in height, the Praga Palm, and Tree Arums, follow the banks of the river even to the subterranean places. There the vegetation continues, as in the deep crevices of the Andes, half shut out from the light of day, nor does it disappear till a distance of 30 or 40 paces from the entrance. The party went forward for about 430 feet without being obliged to light their torches. Where the light began to fail, they heard from afar the hoarse cries of the Guacharo Birds. These birds quit the cavern only at nightfall, especially when there is moonlight; and Humboldt remarks that it is almost the only frugivorous nocturnal bird yet known. It feeds on very hard fruits, and the Indians assured him that it does not pursue either the lammellicorn insects or those *Phalænæ* which serve as food to the goatsuckers. He states that it is difficult to form an idea of the horrible noise made by thousands of these birds in the dark recesses of the cavern, whence their shrill and piercing cries strike upon the vaulted rocks and are repeated by the echo in the depths of the grotto. By fixing torches of copal to the end of a long pole, the Indians showed the nests of these birds 50 or 60 feet above the heads of the explorers, in funnel-shaped holes, with which the cavern-roof is pierced like a sieve.

Once a year, near Midsummer, the Guacharo cavern is entered by the Indians. Armed with poles they ransack the greater part of the nests, while the old birds hover over the heads of the robbers, as if to defend their brood, uttering horrible cries. The young which fall down are opened on the spot. The peritoneum is found loaded with fat, and a layer of the same substance reaches from the abdomen to the vent, forming a kind of cushion between the bird's legs. Humboldt here remarks that this quantity of fat in frugivorous animals, not exposed to the light, and exerting but little muscular motion, brings to mind what has been long observed in the fattening of geese and oxen. It is well known, he adds, how favourable darkness and repose are to this process. At the period above mentioned, which is generally known at Caripe by the designation of 'the oil harvest,' huts are built by the Indians, with palm-leaves, near the entrance and even in the very porch of the cavern. There the fat of the young birds just killed is melted in clay-pots over a brushwood fire; and this fat is named butter, or oil (manteca, or aceite), of the Guacharo. It is half liquid, transparent, inodorous, and so pure that it will keep above a year without becoming rancid. In the kitchen of the monks of the convent of Caripe no other oil is used, and Humboldt never found that it imparted a disagreeable taste or smell to the aliments. The quantity of very pure manteca collected does not exceed 150 or 160 bottles, each being 60 cubic inches; the rest, which is less transparent, is preserved in large earthen vessels: the whole hardly seems to correspond with the immense annual carnage of birds. The use of the Guacharo oil is very ancient, and an Indian family, bearing the name of Morocomas, pretend to be the lawful proprietors of the cavern, as descendants from the first colonists of the valley, and lay claim to the monopoly of the fat; but, when Humboldt wrote, the monks had taken care that their rights were merely honorary. The Indians were obliged, in conformity with the system of the missionaries, to furnish oil of Guacharoes sufficient for the church lamp; the rest, Humboldt was assured, was purchased from them. He observes that the race of Guacharo Birds would have been extinct long since if several circumstances had not contributed to its preservation. The natives, withheld by superstitious fears, seldom dare to proceed far into the recesses of the cavern. Humboldt had great difficulty in persuading them to pass beyond the outer part of the cave, the only portion of it which they visit annually to collect the oil; and the whole authority of the Padres was necessary to make them penetrate as far as the spot where the floor rises abruptly at an inclination of sixty degrees, and where a small subterranean cascade is formed by the torrent. In the minds of the Indians this cave, inhabited by nocturnal birds, is associated with mystic ideas, and they believe that in the deep recesses of the cavern the souls of their ancestors sojourn. They say that man should avoid places which are enlightened neither by the sun nor the moon; and "to go and join the Guacharoes" means to rejoin their fathers—in short, to die. At the entrance of the cave the magicians and poisoners perform their exorcisms to conjure the chief of the evil spirits. It appears also, as another cause of preservation, that Guacharo Birds inhabit neighbouring caverns too narrow to be accessible to man, and from these perhaps the great cavern is repeopled; for the missionaries declared that no sensible diminution of the birds had been observed. Young birds of this species have been sent to the port of Cumana, and have lived there several days, but without taking any food; the seeds offered to them not suiting them. The crops and gizzards of the young birds opened in the cavern contain all sorts of hard and dry fruits, which are conveyed to them by their parents: these are preserved, and, under the name of 'semilla del Guacharo' (Guacharo seed), are considered a celebrated remedy against intermittent fevers, and sent to the sick at Cariaco and other low localities where fever prevails. Our limits will not allow us to pursue Humboldt's description further; and we must content ourselves with referring the reader to the 'Narrative' for many interesting details respecting the cavern itself and the surrounding scenery, giving only in conclusion, the situation, elevation, and temperature of this extraordinary grotto.

The Cueva del Guacharo, then, is situated nearly in 10° 10′ lat., and consequently in the centre of the torrid zone. Its elevation is 506 toises above the level of the Gulf of Cariaco. Humboldt found, in the month of September, the temperature of the interior air in every part of it between 64° 6′ and 66° of Fahrenheit, and the external atmosphere 61° 2′. At the entrance, the thermometer in the air gave 63° 7′; but when it was immersed in the water of the little subterraneous river it stood, even to the end of the cave, at 62° 2′.

GUAIACUM, a genus of Plants belonging to the natural order *Zygophyllaceæ*, and inhabiting several of the West India islands, in low places near the sea. The most remarkable species is *G. officinale*, from which the hard compact black-green wood called Lignum Vitæ is obtained, which is so heavy that it sinks in water, and from which pestles, ship-blocks, rollers, castors, &c. are turned. This plant grows about twelve feet high, with round knotty branches. The leaves are equally pinnate, with about three pairs of opposite, smooth, roundish ovate or obovate oblique leaflets. The flowers are a beautiful bright blue, growing in small axillary clusters. The petals are oblong, downy in the inside, about three times as long as the sepals. There are ten stamens, and an ovate compressed ovary, which becomes an inversely heart-shaped succulent yellow capsule, with from two to five cells, and a single roundish compressed seed in each cell. This plant produces the gum-resin known in medicine under the name of Guaiacum, which is bitter, acrid, and stimulant, partly soluble in water, and wholly in alcohol. It is employed as a diaphoretic and alterative. [GUAIACUM, in ARTS AND SC. DIV.] The foliage is very detersive, and is used in the West Indies to scour and whiten floors, which it is said to do better than soap. Spike cylindrical, elongated; bracts 3-nerved. Flower rose-purple and fragrant. Pollen-cells open in front and below, stopped below by oblong glutinous valves quite distinct from the stigma, and to the broader ends of which the glands of the pollen masses are attached. It is found in hilly pastures.

Guaiacum officinale.
1, a magnified view of the stamens and ovary.

G. albida has a 3-lobed lip, the lobes unequal and entire, the middle lobe longest and broadest; sepals and lateral petals connivent, spur much shorter than the germen, root-knobs clustered. The stem is from 6 to 12 inches high; leaves oblong-obtuse, upper ones lanceolate-acute; the spike elongated, cylindrical; the wood, according to Hernandez, is internally blue. It is called in some of the West Indian Islands Bastard Lignum Vitæ.

G. arboreum is a large tree terminating in a beautiful head, with very hard wood, and is called by the natives of Cumana *Guaiacum*, but they give this name to all hard woods. The leaves have 7 to 14 pairs of oval-oblong blunt leaflets, which are unequal at the base, and are usually alternate, the petioles and branchlets somewhat pubescent; the petals unguiculate, and orange-coloured; the stamens with short appendages at their base; capsules stipitate, 5-winged.

GUAN. [CRACIDÆ.]

GUANITE, a native Phosphate of Magnesia and Ammonia, found by Teschemacher in Guano. It has a specific gravity of 1·5, and a hardness of 2·0. It occurs in brilliant rhombic prisms.

GUANO, the Peruvian name for the droppings of sea-fowl. In some of the islands off the coasts of America and Africa this substance has accumulated in such immense quantities as to have repaid the labour of collecting it and bringing it to Europe, where it is used as a manure. It is now universally admitted to be one of the most valuable of manures, and although it obtains a high price it is increasingly employed in the agriculture of Europe. One of the advantages of this manure seems to arise from the fact that it is produced by animals in which the excretions of both the kidneys and intestines are mixed together, and thus contains a large variety of those matters which are necessary to the existence of plants on which man feeds. The following analysis from Liebig's 'Chemistry in its Application to Agriculture and Physiology,' will give an idea of its ultimate constituents :—

	Sample from Liverpool.	Sample from Lima.
1. Muriate of Ammonia	6·500	4·2
2. Oxalate of Ammonia	13·351	10·6
3. Urate of Ammonia	3·244	9·0
4. Phosphate of Ammonia	6·250	6·0
5. Waxy substance	0·600	,,
6. Sulphate of Potash	4·227	5·5
7. Sulphate of Soda	1·119	3·8
8. Phosphate of Soda	5·291	,,
9. Phosphate of Ammonia and Magnesia .	4·196	2·6
10. Chloride of Sodium	0·100	,,
11. Phosphate of Lime	9·940	14·3
12. Oxalate of Lime	16·360	7·0
13. Alumina	0·104	,,

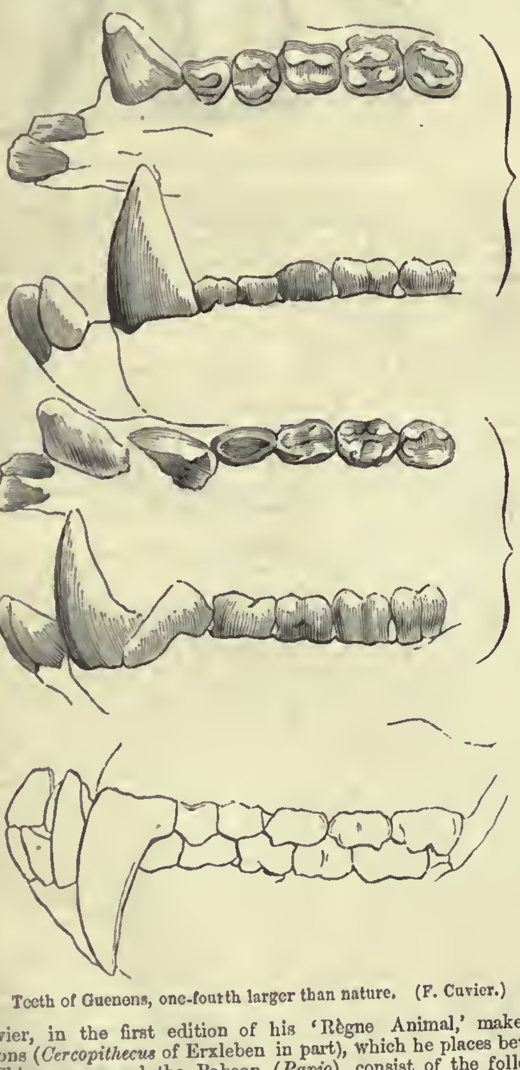
GUAVA. [PSIDIUM.]

GUDGEON. [GOBIO.]

GUELDER-ROSE. [VIBURNUM.]

GUENONS, the French name for a group of Monkeys belonging to the ancient continent and its islands, the type of which may be considered to be the Green Monkey (*Cercocebus sabæus*, Geoff.).



Teeth of Guenons, one-fourth larger than nature. (F. Cuvier.)

Cuvier, in the first edition of his 'Règne Animal,' makes the Guenons (*Cercopithecus* of Erxleben in part), which he places between the Chimpanzee and the Baboon (*Papio*), consist of the following species :—*Simia Entellus*, Dufr.; *S. rubra*, Gmel.; *S. Æthiops*, Linn.; *S. fuliginosa*, Geoff.; *S. Maura*, Linn. (Gmel.?); *S. sabæa*, Linn.; *S. Faunus*, Gmel.; the *Mona* (*S. Mona* and *S. monacha*, Schr.); *S. Diana*, Linn.; *S. Cephus*, Linn.; *S. Petaurista*, Gmel.; *S. nictitans*, Gmel.; *S. Nasica*, Schr. (the Proboscis Monkey, or Kahau); and *S. nemæus*, Linn. (Gmel.?).

In his last edition of the same work he makes the group consist of *S. rubra*, *S. Æthiops*, *S. fuliginosa*, *S. sabæa*, *S. Faunus*, *S. erythropyga*, *S. melarhina*, the *Mona*, *S. Diana*, *S. Petaurista*, and *S. nictitans*, and he places these Guenons between the Gibbons (*Hylobates*, Illig.) and the *Semnopitheci*. M. F. Cuvier, in his 'Histoire des Mammifères,' had expressed his doubts of the propriety of placing the Entellus Monkey among the Guenons, and in his work 'Des Dents des Mammifères' (1825) had separated the *Semnopitheci* from them.

Mr. Swainson ('Classification of Quadrupeds,' 1835) excludes Man from the zoological circle, and makes the *Quadrumana*, Four-Handed Quadrupeds, the first order of the class *Mammalia*. Of this order the *Simiadæ*, Ape-Monkeys, form, according to him, the first family, which consist of—1, "*Simia* (Linn.), Oran-Outang," = *Simia*, *Troglodytes*, *Hylobates*, *Presbytes*, *Pithecus*; 2, "*Cercopithecus*, Pouched Monkeys," = *Lasiopyga*, *Semnopithecus*, *Colobus*, *Cercopithecus*, *Cercocebus*, *Nasalis*. The other genera are *Innuus*, *Macacus*, and *Papio*. In the table of 'Typical analogical Characters,' *Cercopithecus* is placed opposite to *Feræ*.

For Mr. Ogilby's arrangement, see CHEIROPODA.

In this article we shall confine ourselves to M. F. Cuvier's second division of the true Guenons.

Dental formula:—Incisors, $\frac{4}{4}$; canines, $\frac{1-1}{1-1}$; molars, $\frac{5-5}{5-5} = 32$.

The true Guenons comprise the genera *Cercopithecus* and *Cercocebus* of Geoffroy. Nearly similar in manners and in their dentition, particularly with regard to their canine teeth, these genera appear to be naturally allied to each other, though the facial angle and more elongated muzzle, the large cheek-pouches, and shorter tail of the second sub-division (*Cercocebus*) seem to lead gradually to the baboons.

Cercopithecus.—Nearly allied to *Semnopithecus** [SEMNOPITHECUS] in form and manners, but differing from both *Semnopithecus* and *Cercocebus* not only in the development of the dentition, but in the size of the facial angle, which ranges from 50° to 55°, in the flat nose, in the rounded head, and long posterior extremities.

C. Mona, the Varied Monkey of Pennant, Le Singe Varié of Brisson, La Mone and Guenon Mone of Buffon and the more modern French zoologists.

Varied Monkey (*Cercopithecus Mona*). F. Cuvier.

Buffon is of opinion that this species is the Κῆβος of Aristotle, on what ground it is difficult to imagine, for Aristotle only says—'Εστὶ δ' ὁ μὲν κῆβος, πίθηκος ἔχων οὐράν—"the *Cebus* is a *Pithecus* (or Ape) having a tail." ('Hist.' lib. ii. c. 8.) Pennant indeed gives 'Κῆβος?' (with an interrogation) among the synonyms of the Varied Monkey; but in his text he shows that he was aware upon what slender data Buffon assumed its identity with the Κῆβος of the Greeks. Buffon refers also to Ludolf's curious account ('History of Ethiopia') as applying to this monkey, with as much probability as distinguishes his reference to Aristotle. "Of apes," says Ludolf, or rather his book 'made English by J. P. Gent' (1682), "there are infinite flocks up and down in the mountains themselves, a thousand and more together; there they leave no stone unturn'd. If they meet with one that two or three cannot lift they call for more ayd, and all for the sake of the worms that lye under; a sort of dyet which they relish exceedingly. They are very greedy after emmets. So that having found an emmet-hill, they presently surround it, and laying their fore

* Fossil remains of *Semnopithecus Entellus*, the Entellus Monkey, have been found in India.

paws with the hollow downward upon the ant-heap, as fast as the emmets creep into their treacherous palmes they lick 'em off with great comfort to their stomachs; and there they will lie till there is not an emmet left. They are also pernicious to fruit and apples, and will destroy whole fields and gardens, unless they be carefully looked after. For they are very cunning, and will never venture in till the return of their spies, which they send always before, who giving information that all things are safe, in they rush with their whole body, and make a quick dispatch. Therefore they go very quiet and silent to their prey, and if their young ones chance to make a noise they chastise them with their fists; but if they find the coast clear, then every one hath a different noise to express his joy. Nor could there be any way to hinder them from further multiplying, but that they fall sometimes into the ruder hands of wild beasts, which they have no way to avoid but by a timely flight, or creeping into the clefts of the rocks. If they find no safety in flight they make a virtue of necessity, stand their ground, and filling their paws full of dust or sand, fling it full in the eyes of their assailant, and then to their heels again." Such is the account upon the strength of which Buffon makes his reference; but that is not all, for the translation at least is graced by a large plate illustrative of these wonderful scenes, and there is not the vestige of a tail among the whole party of apes, twenty-six in number.

This species has the following characters:—Top of the head greenish-yellow mixed with a slight tinge of black; neck, back, and sides of a deep chestnut brown, passing downwards as far as the shoulders and haunches, where it changes into a dusky slate-colour continued on the limbs and tail, which last is considerably longer than the body, and has on each side of its base a remarkable white spot. Under surface of the body and inside of the limbs pure white, separated from the neighbouring colours by an abrupt line of demarcation. Naked upper part of the face, comprehending the orbits and cheeks, bluish purple. Lips, and so much of the chin as is without hair, flesh-coloured. On the sides of the face large bushy whiskers of a light straw-colour mixed with a few blackish rings advance forwards and cover a considerable portion of the cheeks. Above the eye-brows a transverse black band, extending on each side as far as the ears, and surmounted by a narrow crescent-shaped stripe of gray, which is sometimes scarcely visible. Ears and hands livid flesh-colour. (Bennett, 'Gardens and Menagerie of the Zoological Society of London,' vol. i.)

Mr. Bennett remarks that the name of Mona appears to be of Arabian origin, and is indiscriminately applied, under various modifications, by the Moors of Northern Africa to all the long-tailed monkeys without exception. From the language of the Moors, he observes, it has passed into those of Spain and Portugal, in both of which it has precisely the same signification. Mr. Bennett however does not agree with Pennant and Buffon, who consider it, in its Egyptian form of Monichi, to have been the origin of the English word monkey, which appears to him to admit of a much more obvious, though not very flattering derivation, from the parent-stock of our native tongue. He also expresses his doubts of the accuracy of Buffon in referring the *Cebus* of the ancients to this particular species, to which principally, on account of its being a native of the north of Africa, the latter has restricted the previously generic name of Mona.

Barbary is generally supposed to be the native place of this monkey. They are brought from Africa, and bear a European climate well, whence it is conjectured that they inhabit the north of Africa, or dwell in mountainous districts.

In a state of nature it is not known; for Ludolf's account, to which Buffon refers, cannot, as we have endeavoured to show, be applied with any degree of certainty to this species. M. F. Cuvier gives a very entertaining account of its manners in captivity. The individual which he figures and describes from the Paris menagerie appears to have been most amiable and intelligent, and to have been distinguished for its dexterity in unlocking chests or drawers, untying knots, searching pockets, &c. The individual in the possession of the Zoological Society from which Mr. Bennett's description was taken was capricious, savage in temper, and altogether of a worse character.

Cercocebus.—Resembling *Cercopithecus* in some points, but differing in others. Facial angle about 45°. Head inclined to the triangular form; muzzle rather lengthened; nose flat or convex; thumbs of the anterior hands slender, and placed near the fingers; those of the hinder extremities larger, and placed at a greater distance. Pygal callosities large.

It is the *C. sabæus*, Singe Vert, of Brisson; *Samia sabæa* of Linnæus; Green Monkey of Pennant; St. Jago Monkey of Edwards; Guenon Callitriche, and Callitriche, of the French zoologists.

It is greenish-yellow above, arising from the ringing of the hairs with various shades of yellow and black, but assuming more of a dark grizzled appearance on the sides of the body and outer sides of the limbs, which become gradually darker towards the hands. The face, ears, and naked parts of the hands jet black, the face triangular, bounded above the eyes by a straight line of stiff black hairs, and on the sides by spreading tufts of light hairs with a yellowish tinge, meeting in a point beneath the chin. Neck and chest white; under parts of the body of a yellowish tinge; inside of the limbs gray. Length of head and body 16 or 18 inches; that of the tail somewhat more. (Bennett, 'Gardens and Menagerie of the Zoological Society,' vol. i.)

In Adanson's 'Voyage au Senégal' will be found a good account of the habits of the species in a state of nature, and their silent and unflinching endurance of wounds and death from the gun. They associate in large troops, and are scarcely to be traced among the boughs except when they occasionally break some of them in their gambols, which are performed in silence, though marked by great agility. When shot at they make no noise, but gather together in companies, knit their brows, and gnash their teeth, as if they meant to attack the enemy. In captivity their disposition in general is not amiable, and they are considered captious and malicious; but, as Mr. Bennett observes, much of their character, as in other species, depends on their age and education.

Green Monkey (*Cercocebus sabæus*). F. Cuvier.

They are found in Africa (forests of Mauritania) and the Cape de Verd Islands. Edwards figured his specimen from an individual that was brought from St. Jago. Brisson appears to have been the first describer of the species from a specimen in the museum of Réaumur. Pennant says that it is also found in the East Indies, and that Sir Ashton Lever had his specimen from thence. [SIMIADÆ.]

GUEVI. [ANTILOPEÆ.]

GUEVINA. [XYLOMELON.]

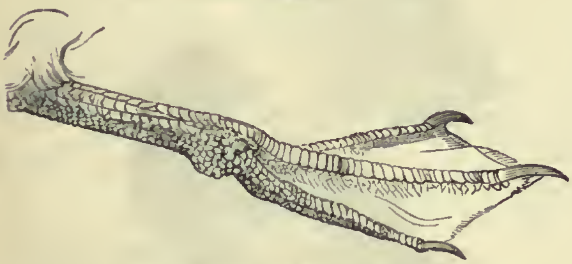
GUILLEMOTS, the common name of the species of *Uria*, a genus of Sea-Birds which some ornithologists place among the family of Divers, or *Colymbidæ*. Linnæus places the species *Grylle* and *Troile* at the head of his genus *Colymbus*. Cuvier arranges the genus under his family Plongeurs, or Brachyptères. Prince Bonaparte arranges them in the second section of his family Pygopodes, the genus *Colymbus* forming the first section. Lesson makes them belong to the family *Alcadæ*, which he seems to consider as synonymous with the Plongeurs of Cuvier.

Mr. Vigors, on leaving the *Colymbidæ*, enters the family of *Alcadæ* by means of the genus *Uria* (Briss.), which was originally included in the *Colymbus* of Linnæus, and from which, he observes, it has been separated chiefly on account of the tridactyle conformation of its foot. This character distinguishes the greater part of Mr. Vigors's group of *Alcadæ*, which, in addition to *Uria*, contains the genera *Alca* [AUK], and *Aptenodytes* [PENGUIN] of Linnæus. The latter genus, Mr. Vigors remarks, apparently carries to the extreme the typical character of those groups in which the wings, becoming gradually shorter, and less furnished with feathers, lose at length all their powers of flight, and assume the functions of fins, instead of wings, to assist the bird in its progress through the water. The whole of the family, united by the form of the foot, is separated into generic groups by the different shape of the bill. "And here," continues Mr. Vigors, "a beautifully progressive series of affinities is apparent throughout the whole group. Beginning from the true *Aptenodytes*, we may observe that the bill of that genus is long, rather slender, and somewhat curved; while that of *Catarrhactes* (Briss.), which succeeds, is shorter and more elevated at the ridge; thus leading the way to *Spheniscus* (Briss.), where the sides are compressed, and the culmen elevated into a sharp edge. This structure approaches the form of the same member in the true *Alca* [AUK], in which the sides are still more strongly compressed, and the culmen more elevated. The *Fratercula* (Briss.), the well-known Puffin of our rocky coasts [AUK], following *Alca*, exhibits the extreme of this singular construction; and there cannot be a more interesting subject of contemplation to him who may wish to witness the mode in which nature harmonises her groups, than the gradual change of form that unites the short and elevated bill of this last genus with the long aud slender bill of *Aptenodytes.* A similar gradation of affinities between conterminous groups leads us back again to the point from whence we started. Some species of the Linnæan *Alca*, which M. Temminck has united under the generic title of *Phaleris* [AUK], with bills less elevated at the culmen, and more tapering than that of *Fratercula*, lead us gradually to the *Mergulus* of Ray, the Little Auk of our cabinets. [AUK.] This genus, strongly and distinctively separated both from *Alca* and *Uria*, in the former of which groups it has been placed by Linnæus, and in the latter by M. Temminck, may be considered as intermediate between them. It thus brings us to *Uria*, where the pointed and tapering hill, again discernible, reconducts us to *Aptenodytes*." ('Linn. Trans.,' vol. xiv.)

Mr. Swainson, in the first part of the second volume of ths 'Classification of Birds,' appears to differ from Mr. Vigors, for he arranges the Guillemots, together with the Divers and Grebes, under the *Colymbidæ*. The *Alcidæ* (*Alcadæ*) include, according to the same author, the Penguins and the Puffins, and "all those singularly constructed groups where the wings are abortive, or in other words assume more the appearance, as they perform the office of fins;" but he remarks that the natural series of the genera have been commenced by some with *Uria;* by others, with some of ths *Alcæ*, or Pnffins. In the 'Synopsis' however, at the end of the volume, we find *Uria* the first genus of the 'family *Alcadæ:* Auks,' with the observation that the individuals in this group are so few that ths author has not considered it expedient to adopt the sub-genera, particularly as their natural series has not been marked out. The gencra which Mr. Swainson here places under the family *Alcadæ* are —*Uria*, Briss.; *Alca*, Linn.; *Mormon*, Ill.; *Chimerina*, Esch.; *Phaleris*, Temm.; *Aptenodytes*, Forst.

Uria.—Bill moderate, robust, straigbt, acnte, and compressed; upper mandible slightly curved towards the point; the lower mandibls forming an angle more or less open. Nostrils basal, lateral, concave, longitudinal, pervious, half shut by a large membrane covered with feathers advancing on the bill. Feet short, plunged as it wsre in the abdomen, so that the lower end of the tibia only is perceptible, and placed beyond the equilibrium of the body very far back; tarsi short, slender; three toes only, all anterior and entirely wsbbed: nails compressed, rather curved and sharp; wings short, narrow, and acute, the first quill longest; tail very short, rounded.

Bill of Common Guillemot (*Uria Troile*).



Foot of Common Guillemot (*Uria Troile*).

The Guillemots seem especially framed for existence in the arctic and even polar regions, and are seldom, comparatively, found in the warmer latitudes. In the north they swarm on all the rocks and islets of the chilling seas. In the short but bright summer that gilds some of their northern haunts, they make haste to deposit their eggs, sometimes only one, on the bare rock, without wasting ths precious days in making a nest. On the naked ledge that overhangs the sea the young Guillemot is hatched, and as soon as it is able to bear the shock, is conducted or rather tumbles from its hard nursery into the bôsom of the ocean, where a plentiful harvest is spread for it. Here the Guillemots are indeed in their element; plying their way with wings and feet beneath the waves and evsn beneath the ice, they make prey of the small fish and crustaceans, which form their principal food. Their native rocks or the ice-caverns shelter them from the storm, and it is only when the winter is mors than hyperboreally severe that soms of these species are driven for a temporary resort to more temperate climates. Their flight is sharp and rapid, though of no long duration, and generally directed just above the surface of the sea. The eggs, which are reckoned palatable, notwithstanding their fishy diet, are thick in the shell, which has a dull appearance.

Sir John Richardson notices *Uria* (*Mergulus*) *Alle* [AUK], among the species which merely winter in Pennsylvania, and migrate in summer to rear their young in ths Fur Countries—*Uria Brunnichii*, *U. Grylle*, and *U. Alle* in his list of birds detected in the North Georgian Islands and adjoining seas, iu 73° to 75° N. lat., on Sir Edward Parry's first voyage—and *U. Brunnichii*, *U. Troile*, *U. Grylle*, and *U. Alle* in the list of species common to the Old World and to the Fur Countries. *U. Alle*, *U. Brunnichii*, and *U. Grylle* occur in the list of 'Greenland Birds' by Col. Sabine.

In the table published by Sir John Richardson in 'Fauna Boreali-Americana,' the following interesting information is given :—

Species.	Extreme Northern range. Distribution in the Fur Countries. Whether resident or migratory.	Species that frequent the vicinity of Philadelphia. C. Bonaparte.	Winter Quarters of the Species.
	Lat. N.		
Uria Troile . . .	61°. Arctic Sea and Hudson's Bay.	Accidental visiter.	Principally at sea, in high latitudes.
Uria Brunnichii	75°. Arctic Sea and Hudson's Bay.	Accidental visiter.	Principally at sea, in high latitudes.
Uria Grylle . .	75°. Arctic Sea and Hudson's Bay.	Accidental visiter.	Principally at sea, in high latitudes.
Uria Alle . . .	75°. Arctic Sea and Hudson's Bay.	Winter. Rather rare.	United States.

Captaiu Sir James Ross ('Supplement to Sir John Ross's Last Voyage') says that *Uria Brunnichii* abounds in Baffin's Bay, and is found iu most parts of the arctic seas, and that he has also met with the species at Uist, ths northernmost of ths Shetland Islands, and in several parts of Scotland; but he observcs that it has always been confounded hy authors with *U. Troile*, which it so nearly resembles. He further states, that *Uria Alle* (Littls Guillemot, Little Auk of authors) collects during the breeding ssasou in vast numhers along the north and east coast of Baffin's Bay, but is seldom to be met with far to the westward of Lancaster Sound. A few were seen by the expedition near Leopold Island, and two or three specimens were obtained.

U. Troile, the Common Guillemot, Willock, or Tinkershere. Description of hoth sexes (old) in their winter dress.—Summit of the head, space between the eye and the bill, longitudinal band behind the eyes, and all the upper parts, of a velvety black slightly inclining to ash: all the lower parts and the extremity of the secondaries pure white: white is also found between the band behind ths eyes and the back of the nape, and advances towards the occiput, where it forms on each side an open angle. The ashy blackish colour of the lateral part of the neck seems to form towards ths breast a kind of collar, feebly indicated by bright ash. Bill ashy black; inside of the mouth livid yellow; iris brown; fset and toes yellowish-brown; posterior part of the tarsus and membranes black. Length from the bill to the claws rather more than 15 or 16 inches. N.B. The female is rather less than the male. In this stats Temminck, whoss description we have given, considers the bird to be *U. Suarbag* aud *Ringuia* of Brünnich; *Colymbus minor* of Gmclin; Lesser Guillemot of Pennant; Der Dumms Lumme of Bechstein; and Troillumme of Meyer.

Summer or Nuptial Plumage.—Head, region of the eyes, throat, and all the upper part of the neck of a velvety brown; inside of the mouth bright yellow: the rest of the plumage as in winter. Thus clad it is *Uria Lomvia* of Brünnich; *Colymbus Troile* of Linnæus and Gmelin; Le Guillemot of Buffon; Foolish Guillemot of Latham; Uria Maggiore, 'Stor. degl. Ucc.' (Temminck).

Young of the Year.—Principally distinguishsd from ths old birds in thcir winter plumage, by the comparativs shortness of the bill, which is ashy and yellowish at the hass; the black of the upper parts is clouded with ash-colour; the stripe or longitudinal band is not distinct, and mingles by means of ashy spots, with the white of the sides of ths occiput. Ashy-brown predominates on the lower parts of ths neck, and the white of ths lower parts is not so pure; the tarsi and toes are of a livid yellowish hue. It is then *Colymbus maculâ nigrâ pone oculos*, 'Sander. Naturf. Gmel.,' i. p. 584, va. *β*. (Temminck).

Accideutal Varieties.—No white on the secondary quills. M. Temminck states that hs killed an old Guillemot in ths spring, which had the whole of ths back and the caudal feathers mottled with yellowish-ashy stains.

This species is the Gwilym and Chwilog (the latter term applicable to ths stats in which Pennant calls it ths Lesser Guillemot) of the Welsh, and is called Willock in the South of Englaud, Skout iu Yorkshire, and Kiddaw in Cornwall. The number of provincial names is very great.

This bird is found in ths arctic seas of the Old and the New Worlds; migratory in winter iu largs companies along the coasts of Norway and England; very common at that tims along the shores of the Baltic and the maritime coasts of Holland and France; more rarely fouud "upon our seas aud great lakes of the interior." (Temminck.) Spitzbergen, Lapmark, and the White and Icy seas as far as Kamtschatka. Along the whole coast of Hudson's Bay, Labrador, and Newfoundland. (Nuttall.) The great body of the American birds of this species winter in the Bay of Fundy. (Audubon.)

In the British Islands they are numerous (among other localites) in the Orkneys, on the Bass Rock, the Farn or Fern Isles, the cliffs of Scarborough, the Needles and cliffs of the Isle of Wight, the Goodeve Rocks not far from St. Ives in Cornwall, and the Isle of Priestholm, contiguous to the Island of Anglesey, &c.

Common Guillemot (*Uria Troile*).
An adult and a young bird of the year.

The appellation of Foolish Guillemot has been given to this species from its often suffering itself to be taken by the hand or killed on the spot, especially in the breeding season, rather than quit the cliff it has chosen for its abode. The sea is the favourite resort of these birds when they leave their cliffs, and there they seek their food, consisting principally of small fish, small marine crustaceans, and small bivalves, diving with the greatest facility. They are with difficulty roused to flight. Early in April and May, or at the end of March, they begin to assemble on their favourite cliffs in Britain, and lay their single unprotected egg on the flat bare ledge of rock. This egg is generally of a pale green, blotched and stained with black and dark brown (umber). Sometimes the egg is white, with or without a few spots. It is a remarkable sight to see these birds, where they abound, sitting upon their eggs on their rocky shelves, often in line, and so close that they nearly touch each other. As soon as the young are capable of migrating, which is in August, or by the end of that month, they are said to disappear from our shores. Mr. Selby, whose obervations are always valuable, gives the following interesting account of these birds:—"Incubation lasts for a month, and when the young are first excluded they are covered with a thick down, of a blackish-gray colour above, and white beneath. This gradually gives place to the regular plumage, and in the course of five or six weeks from the time of hatching they are capable of taking to the water. During the time they remain upon the rock the parents supply them plentifully with the young of the herring and herring-sprats, which form the principal food of this and other species belonging to the *Alcadæ*. Upon the Northumbrian coast these Guillemots breed in great numbers on the Fern Islands, a locality that has afforded me ample opportunities of attending to their economy and watching the changes they undergo. They have selected the summits of three fine isolated pillars, or masses of 'whinstone' (trap-rock), that rise upwards of thirty feet above the level of the sea. Upon these the eggs are laid as close as possible, merely allowing room for the birds to sit upon them, which they do in an upright position. The appearance they make in a dense mass is curious, and the interest is increased by the number of Kittiwakes (*Larus tridactylus*) which hover around, and which breed in the small side clefts, or on the projecting angles of the rock; and by the nests of two or three Crested or Green Cormorants, which, from the unusual confidence they display in continuing to sit upon their eggs, even when overlooked from the opposite precipice at only a few yards' distance, seem to be well aware of the security of the station they have chosen. The great body of the breeding birds arrives towards the end of March, or the beginning of April, at which time most of them have acquired the perfect nuptial plumage. I have however obtained them much earlier, and when the white upon the throat was only giving place to the pitch-coloured black that distinguishes them till after the sexual intercourse. At this time they often lose so many of their quill-feathers as to be totally incapable of flight; but these are soon reproduced, and the colonies which had made the English coasts their summer quarters retire to more southern latitudes to pass the winter months. Their place in this country is but sparingly supplied by a few stragglers from the great bodies that, being bred in still higher latitudes, make the firths of Scotland and its isles the limit of their equatorial migration." ('Illustrations of British Ornithology,' vol. ii.)

Much cannot be said in favour of the flesh of the Foolish Guillemot, though the people of Kamtschatka kill numbers of those birds for food. The principal reason however for the attack upon them arises from the value of their skins as an article of clothing to the inhabitants of those cold regions. The eggs seem to be generally accounted delicacies.

U. Grylle, the Black Guillemot. Description of both sexes in complete winter plumage.—Summit of the head, nape, and all the upper parts, with the exception of the middle of the wings, of a rather deep black; the wing-coverts forming a large white space, or speculum. Cheeks and all the lower parts from bill to tail pure white; irides red.* Bill black; interior of the mouth and feet bright red. Length from bill to claws about 13 inches. In this state M. Temminck, whose description we have selected, says that *U. minor striata* of Brisson, *U. Baltica* and *U. Grylloides* of Brünnich, are individuals in different stages of moulting, passing from winter plumage to that of summer; that the Spotted Greenland Dove of Edwards ('Glean.,' t. 50) is a very exact figure of a moulting individual; and that the Spotted Guillemot of the 'British Zoology' and Latham ('Syn.') are varieties or different states of the autumnal and spring moults.

Black Guillemot (*Uria Grylle*).
An adult and a young bird.

Young of the Year.—Throat, breast, and the lower parts, white; summit of the head, nape, lower part of neck and sides of the breast, blackish, spotted with gray and white; back and rump of a dusky black, some of the scapulars and feathers of the rump terminated with whitish ash; wings black, with the exception of the speculum, which is white, but marked with ashy or blackish stains; inside of the mouth and feet livid reddish; iris blackish-brown.† In this state

* Temminck says brown; but Mr. Gould ('Birds of Europe') describes and figures them as red in the adult, and this we believe to be right.

† In our copy of Frisch the iris is coloured red. In Mr. Gould's 'Birds of Europe' the iris is brownish, inclining to olive, and the feet are yellowish-brown.

there is a very faithful figure of the bird in Frisch, 'Vög. Deutsch.,' t. 185 (Temminck).

Summer Plumage, or Nuptial Dress.—Male.—The whole plumage, the middle of the wing alone excepted, of a sooty-black; wing coverts forming a large space or speculum of pure white. Bill black, the inside of it and the feet bright red.

Female.—Rather less. The black of the plumage less deep, and the white of the plumage less extended and less pure. At the periods of the two moults white feathers in more or less quantity are visible on the under parts of both sexes. M. Temminck, who gives this description, refers to the following synonyms and works as illustrative of this state of plumage, and some of its stages: *U. Grylle*, Lath.; *Colymbus Grylle*, Gmel. (Linn.?); *Columba Grœnlandica*, Briss.; Le Petit Guillemot Noir, Buff.;* Black Guillemot, Lath. ('Syn.'); Penn. 'Brit. Zool.,' p. 138, t. H. 4, an individual preserving some of the feathers of its youth; Penn. 'Arct. Zool.,' p. 516, No. 437—Edw., 'Glean.,' t. 50.; Der Schwarze Lumme, Bechst., 'Naturg. Deutsch,' v. iv. p. 586—Meyer, 'Taschenb.,' vii. p. 446—Meyer, 'Vög. Deutschl.,' v. i.—Heft, 13, t. 3 and 4—Naum, 'Vög.,' t. 64, No. 6. f. 100, very old male.

M. Temminck remarks that the indications of the pretended species, *Cephus lacteolus* (Pallas, 'Spic.' v. 5, p. 33), which Latham has recorded as his *Uria lacteola* ('Ind.' v. 2, p. 798, sp. 3)—*Colymbus lacteolus* (Gmel.)—have reference to an individual in its winter plumage, accidentally variegated with white; and that this albino was obtained by Pallas on the maritime coasts of Holland.

Mr. Selby observes that from the short description given by Cuvier of his genus *Cephus*, in the 'Règne Animal,' it is evident that the Rotche, or Little Auk, of some of our writers (*Alca Alle*) is there considered to be its typical representative, and not the Black Guillemot; and, he observes, this appears still more evident from the note at the bottom of the same page, in which (after adverting to the figures of the Lesser and Spotted Guillemots in the second volume of Pennant's 'British Zoology,' pl. 83) Cuvier says, "Ces sont des Guillemots proprement dits. Au contraire, *l'Alca Allé*, Penn. ('British Zoology,' 11, pl. 82, 1; Albin, 1, 85), appartient aux *Cephus*." Mr. Selby goes on to remark that Dr. Fleming has however appropriated this generic term to the Black Guillemot, making the distinction between it and *Uria* to consist in the want of a terminal notch in the upper mandible; but as this character does not appear to be constant, Mr. Selby having seen some specimens with the notch, though not so fully developed as in the Foolish Guillemot, he has retained it in the situation where it was originally placed by Dr. Latham.

The note alluded to by Mr. Selby is in the first edition of the 'Règne Animal;' but in Cuvier's last edition (1829), which Mr. Selby does not appear to have seen, the note is omitted. In this edition the generic appellation "*Cephus* (Vulg. Colombes de Groenland)" is retained with the same characters, but the subsequent part is very much altered, for it stands thus in the last-mentioned edition:—"The species most known, called Petit Guillemot, or Pigeon de Groenland (*Colymbus minor*, Gm. Enl. 917; *Mergulus Alle*, Vieill., Gal. 295; 'Brit. Zool.' pl. H. 4, f. 1; Edw. 91; Naum. 1st ed. 65, f. 102), of the size of a good pigeon, is black above, white below, with a white mark on the wing as in the Guillemot. Its bill is black and its feet are red. It inhabits all the coasts of the north, and nestles under ground ('niche sous terre'). We see it also sometimes in winter." Notwithstanding the confusion in the passage just quoted, and some parts of the description, references, and alleged nidification which can hardly be made to apply to the Little Auk, or Rotche, it seems probable that Cuvier meant to take that bird, as Mr. Selby observes, as the type of his genus *Cephus*.

It is also called the Black Greenland Dove, Sea-Turtle, or Dovekey, by the northern voyagers; is the Sesekesewuck of the Cree Indians, and Gwylim dû Eas gan longwr of the Welsh.

It inhabits the same countries as *Uria Troile;* migratory during winter along the borders of the ocean; more rarely seen on land than *Uria Troile*, and then only by accident; very rare in the seas and lakes of the interior. (Temminck.) Widely distributed in the arctic circle, and met with in very high latitudes, inhabiting all the icy regions of Europe and North America. (Selby.) Abounds in the arctic seas and straits from Melville Island down to Hudson's Bay, and remains, though in diminished numbers, all the winter in the pools of open water, which occur even in high latitudes among the floes of ice. Small flocks extend their migrations, in that season, as far south as the United States. (Richardson.)

Mr. Selby observes that in the northern parts of Scotland and its isles this is a numerous species, but becomes of rarer occurrence as we approach the English coast, where indeed it is but occasionally met with. "Although Montagu," continues Mr. Selby, "has mentioned it as resorting to the Farn Islands, and Mr. Stephens has repeated the same, I can safely assert that this has not been the case for the last twenty-five or thirty years, having been in the habit of visiting this group of islands almost annually during that period; and had it been a visitant I feel confident it could not have escaped my observation, or that of the keepers of the lighthouse, who reside there. It certainly breeds, though in very small proportion, upon the Isle of May, at the mouth of the Frith of Forth, but is not found in large congregated numbers till we reach the vicinity of the Orkney and Shetland isles. In these parts it is resident throughout the year, never migrating to the same extent as the preceding species (*Uria Troile*) and the Razor-Bill Auk. Its habits are very similar to those of its congeners, and it is rarely seen upon land, except for the purpose of incubation. It breeds in the crevices or on the ledges of rocks, whence it can readily drop into the water or get upon wing, and lays a single egg, of a grayish-white, speckled with black and ash-gray. Its food consists of fish, *Crustaceæ* (*Crustacea*), &c." So far Mr. Selby, with whose accuracy as an observer we have often had occasion to be satisfied. Mr. Gould moreover speaks of its depositing on the ledges of the rocks "its single egg." We must however now let one of the most indefatigable observers speak for himself, more especially as his account differs so essentially from those above mentioned, and indeed from those of most other authors, except Nuttall. "Wherever," says Audubon, "there are fissures in the rocks, or great piles of blocks with holes in their interstices, there you may expect to find the Black Guillemot. Whether European writers have spoken of this species at random, or after due observation, I cannot say; all I know is, that every one of them whose writings I have consulted says that the Black Guillemot lays only one egg. As I have no reason whatever to doubt their assertion, I might be tempted to suppose that our species differs from theirs, were I not perfectly aware that birds in different places will construct different nests, and lay more or fewer eggs. Our species always deposits three, unless it may have been disturbed; and this fact I have assured myself of by having caught the birds in more than twenty instances sitting on that number. Nay, on several occasions, at Labrador, some of my party and myself saw several Black Guillemots sitting on eggs in the same fissure of a rock, where every bird had three eggs under it; a fact which I communicated to my friend Thomas Nuttall. What was most surprising to me was, that even the fishermen there thought that this bird laid only a single egg; and when I asked them how they knew, they simply and good-naturedly answered that they had heard so." The same graphic author addressing the reader tells him, in order to satisfy himself, to go to the desolate shores of Labrador. "There," continues the American ornithologist, "in the vernal month of June, place yourself on some granite rock, against the base of which the waves dash in impotent rage; and ere long you will see the gay Guillemot coming from afar by the side of its mate. They shoot past you on fluttering wings, and suddenly disappear. Go to the place; lay yourself down on the dripping rock, and you will be sure to see the birds preparing their stony nest, for each has brought a smooth pebble in its bill. See how industriously they are engaged in raising this cold fabric into the form of a true nest before the female lays her eggs, so that no wet may reach them from the constant trickling of the waters beneath. Up to the height of two or three inches the pebbles are gradually raised: the male stands by his beloved; and some morning when you peep into the crevice you observe that an egg has been deposited. Two days after you will find the number complete." ('Ornithological Biography,' vol. iii.)

Captain Sir James Ross, R.N., who in March 1823 shot near Igloolik the specimen described by Sir John Richardson, says that one individual only was obtained by the expedition during the winter, although several others were seen off Fury Point in February, 1833. It was, he adds, subsequently met with in great numbers as they travelled along the high precipitous land between Fury Point and Batty Bay, where the birds congregated in vast quantities during the breeding season, affording to the party many delicious meals, and proving a valuable addition to their then scanty stock of provisions. Several thousands were shot by their sportsmen; and by means of this providential supply of fresh food several of the men, who had been long afflicted with that most dreadful malady the sea-scurvy, were restored to health. Captain Sir J. Ross adds that it is not equal in flavour to *Uria Troile*, but is much more numerous and more extensively dispersed along the coasts of the arctic seas.

The species of this genus are but few. Speaking of *Uria lachrymans*, the Bridled Guillemot, Mr. Gould, in his 'Birds of Europe,' where it is beautifully figured, states that he is doubtful of its specific value, as it bears so close a resemblance to *U. Troile*, from which it differs only in the white mark which encircles the eyes and passes down the sides of the head. It inhabits the same localities as *U. Troile*, and is even often found in company with it on various parts of our coast, particularly in Wales, where Mr. Gould has been informed both kinds are equally numerous. He remarks that it was first described as distinct by Choris, who states that it is abundant at Spitzbergen and in the neighbouring seas; and adds that M. Temminck and the French naturalists consider these two *Uriæ* distinct.

U. Brunnichii, Brünnich's Guillemot, the Thick-Billed Guillemot. The distinctions of this species have been well pointed out by Colonel Sabine in his memoir on the birds of Greenland. It is at once distinguished at any season of the year from the Common Guillemot by the shortness, stoutness, regularity, and greater depth of its bill. It is on this account that it has been called the Thick-Billed Guillemot. This bird is recorded to have been occasionally seen in the British Islands. It has the habits of the Common Guillemot.

* M. Temminck speaks of Buffon's description as being correct, but not so the figure in the 'Planches enluminées' (917).

GUINEA-FOWL. [PHASIANIDÆ.]

GUINEA-PEPPER, the seeds of two species of *Amomum*, found on the west coast of Africa, within the tropics; the one, *A. grana Paradisi*; the other, *A. grandiflorum*. They are powerfully aromatic, stimulant, and cordial, and are used for the same purposes as Cardamoms.

GUINEA-PIG (*Cavia Cobaya*, Restless Cavy), the well-known Brazilian rodent now domesticated in Europe. [HYSTRICIDÆ.]

GUINEA-WORM. [ENTOZOA.]

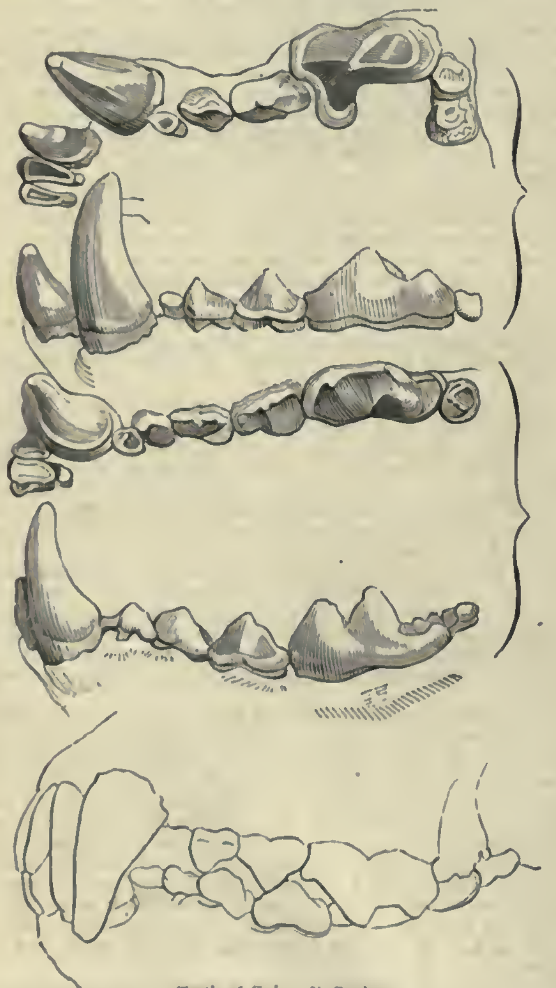
GULL. [LARIDÆ.]

GULO, the generic name under which the Glutton, or Wolverene, and the Grison (*Galictis* of Bell), with other Carnivorous congeners, have been arranged.

M. F. Cuvier, in the 32nd number of his 'Dents des Mammifères,' says that he might have treated of the Grison, the Tayra (*G. barbatus* of Desmarest), and the Glutton, in his preceding article, where he treats of the dentition of the Putois (*Putorius* of G. Cuvier), Zorille (*Zorilla*), and Martes (Martens); for he remarks, the dental arrangement of the Grison and Tayra resemble that of *Putorius*, and that of the Grison is similar to the formula observed in Martes. The two first, he states, have two false molars above and three below, and the last has an additional one in each jaw. For the rest, these animals have nothing in their teeth to distinguish them; that is to say, he continues, they have the same incisives, the same canines, and the same tubercular teeth. They have consequently all a relish for blood, and could not be separated from each other were it not for the plantigrade feet of the Grison, the Tayra, and the Glutton, an organisation which does not however change their propensities, and only leads to the modification of the means by which they satisfy their appetites.

The dental formula of the group has been stated as follows:—

Incisors, $\frac{6}{6}$; canines, $\frac{1-1}{1-1}$; molars, $\frac{4-4}{5-5}$, or $\frac{5-5}{6-6}$, = 34 or 38.



Teeth of *Gulo*. F. Cuvier.

The well-developed carnivorous dentition, united with the plantigrade foot, seems to have thrown a difficulty in the way of zoologists, as to the proper place of these animals in a natural arrangement.

Linnæus placed the Quickhatch (*Ursus luscus*) among the Bears; but he appears to have considered the Glutton of the old continent not only as a different species, but as a different form, under the name of *Mustela Gulo*. This species is preceded by the *M. lutris*, *M. lutra*, *M. lutreola* and *M. barbara*—the latter the *Galera* of Browne, Jam. (?); and at the end of the description of *M. Gulo* Linnæus inquires whether all these species ought not to be referred to the genus *Viverra*. "Cum fata mihi denegarint præmissas species intueri vivas, videant alii numno ad Viverras referri debeant; hoc suadet Lutræ statura; hoc Gulonis fœtor, scansura arborum, summa laniena." ('Syst. Nat.,' ed. 12.)

Baron Cuvier (1817-1829) notices the position among the Bears assigned to the Glutton by Linnæus, but does not allude to its place among the *Mustelæ* of Linnæus, though he observes that the Gluttons approach more to the Martens in their dentition as well as in their general nature, while they only show their proximity to the Bears by their plantigrade feet. They have, he observes, three false molars above and one below in front of the carnivorous tooth (carnassière), and behind it a small tubercular tooth, which in the upper jaw is wider than it is long. The upper carnivorous tooth has only one small internal tubercle, and this, he remarks, is very nearly the dental system of the Martens. He concludes by stating that the Gluttons are animals with a moderate tail, with a fold under it in lieu of a pouch, and in other respects resembling the Badgers in their contour.

Dr. J. E. Gray ('Annals of Philosophy,' 1825) divides the *Ursidæ*, the second of his five families of the order *Feræ*, into five sub-families. The third of these sub-families, which he places in his second section (tubercular grinder 1—1 above and below), is *Gulonina*, and consists of the genera *Gulo*, Retz; *Galera*, Browne; *Grisonia*, Gray; and *Mellivora*, Storr.

M. Lesson (1827), in his 'Manuel,' arranges the genus *Gulo*, Retz, between the Badgers and the Ratel (*Mellivora*, Storr.); and he gives the following definition of the genus:—"Feet pentadactyle; two folds of skin, but no pouch near the vent; body more or less slender (effilé), more or less elevated on the legs; tail rather short." The dental formula stated by Lesson is the same as that above given.

Dr. Fischer (1829) places *Gulo* between *Mydaus* and *Ailurus*.

Mr. Swainson, in his 'Classification of Quadrupeds' (1835), says, "In its general appearance and physiology the Otter is not unlike the ordinary Polecats; and the resemblance is still further strengthened by the latter having semi-palmated or half-webbed toes, and occasionally frequenting the water in search of fish. On the other hand, the Grisson (Grison), *Gulo vittata* (*vittatus*), and the Taira, *G. barbara* (*barbarus*), now placed among the Gluttons, have their feet also semi-palmated; and, observes M. Cuvier, it appears they have sometimes been mistaken for otters. We may thus terminate the series of the *Mustelinæ* with the genus *Gulo*, which, although plantigrade, appears to have an affinity to the Polecats through *Lutra*, while at the same time it may open a passage to the Badgers and Bears." In the same page Mr. Swainson writes, "It will be a question for future investigation whether the Gluttons (*Gulo*), the Rattels (Ratels), *Ratelus*, and the Badgers (*Meles*), form the aberrant portion of the Ursine circle, or whether they merely represent the Bears, and enter into the circle of the *Mustelidæ*. For the present we may consider the two last in the former light, and thus pass onward to the sub-family of *Ursinæ*, typically distinguished from all others of the *Mustelidæ* by their great size, their omnivorous diet, and their short tails." In the third part of the work, "the class *Mammalia* arranged according to its natural affinities," *Gulo* is placed among the *Mustelinæ*, a sub-family which is preceded by *Viverinæ* (*Viverrinæ*?), and followed by *Ursinæ*.

The species of *Gulo* noted by Cuvier are:—1, the Glutton (*Ursus Gulo*, not of Linnæus, as Cuvier quotes it, but of Pallas and Gmelin) of the old continent, which, Cuvier observes, does not appear to differ from the Glutton of North America (*Ursus luscus* of Linnæus); 2, the Grison (*Viverra vittata*, not, as Cuvier quotes it, of Linnæus, who has no such species of *Viverra* in his last edition of the 'Systema Naturæ,' but of Gmelin); and 3, the Taira, or Tayra (*Mustela barbara* of Linnæus).

Lesson admits the following species of *Gulones*:—*G. arcticus* of Desmarest; *Ursus Gulo*, Linn. (Gmel.), &c., the Glutton, with *Ursus luscus*, Linn., as a variety; *G. vittatus* of Desmarest; *Viverra vittata*, Linn. (Gmel.), &c., the Grison; *G. barbatus* of Desmarest; *Mustela barbata* (*barbara*), Linn.; the Taira, or Galera, Grand Furet, of D'Azara; and *G. orientalis* of Horsfield, Nientek of the Javanese.

Dr. Fischer makes the recent species consist of *G. arcticus*, Desm., *G. vittatus*, Desm., *G. barbatus*, Desm., *G. lanatus* and *G. Capensis*, Desm. (the Ratel), observing that this last would be better removed to a distinct genus, and making this general remark on the whole generic assemblage—"Genus e speciebus nimis heterogeneis uti videtur conflatum." In his addenda he introduces *G. larvatus*, Temm. and Hamilton Smith, and *G. ferrugineus*, Hamilton Smith.

The Grison has been separated into a genus, named *Galictis* by Mr. Bell, and *Grisonia* by Dr. Gray, who also distinguishes the Tayra generically under the name of *Galera*, Browne; and observes, on the occasion of defining his genus *Helictis* ('Zool. Proc.,' 1831), that the *Gulo orientalis* of Dr. Horsfield's 'Zoological Researches in Java' appears to him to form a second species of the genus.

Pallas, and after him Pennant, who both arranged the form among the Bears, treat the Glutton of the old and that of the new continent as identical; and indeed zoologists seem now to agree in coming to that conclusion, but the synonyms afford good evidence of the difference of opinion that has prevailed with regard to its proper position.

The Glutton (*Gulo luscus*) is the Carcajou of La Hontan and the French Canadians; Quickhatch (*Ursulo affinis Americana*) of Catesby (Carolina); Quickehatch of the English residents at Hudson's Bay; Quickhatch, or Wolverene, of Ellis; Wolverene of Pennant; Wolverin, Quiquihatch, or Carcajou, of Graham (manuscripts); Kablee-arioo of the Esquimaux of Melville Peninsula; Kā ŏ wēēk of the Esquimaux of Boothia Felix; Naghai-eh of the Chippeways; Ommeethatsees, Okeecoohagew, and Okeecoohawgees (whence, as Sir John Richardson observes, the term Quickhatch of the European labourers in the service of the Hudson's Bay Company is evidently derived), of the Crees, or Algonquins; Rosomak of the Russians; Jarf, Filfress, of the 'Fauna Suecica'; Timmi of the Kamtschatkans; Haeppi of the Koratzki; Glouton of the French; *Gulo* of Olaus Magnus; *Gulo*, Vielfrass, of Gesner; *Hyæna* and *Ursus Freti Hudsonis* of Brisson; *Mustela Gulo* and *Ursus luscus* of Linnæus; *Ursus Gulo* of Pallas and Gmelin; *Taxus Gulo* of Tiedemann; *Gulo arcticus* of Desmarest; *Gulo vulgaris* of Griffith's Cuvier; *Gulo luscus* of Sabine.

Wolverene, or Glutton (*Gulo luscus*).

Olaus Magnus seems to have heen the source whence most succeeding writers have drawn their marvellous accounts of the Gluttou, setting forth its cruel and destructive powers, its inordinate voracity, aud the means which it adopts for filling itself till it is ready to burst, aud for getting rid of the load which it has swallowed. Buffon, who, too prone to censure other writers, and even nature herself, appears to have had almost the appetite of a Pliny for every wonderful tale, eloquently presents the relations of the older writers, not forgetting Ysbrandt, describiug the Glutton as a ferocious animal, prompt to attack the larger quadrupeds, and even fearlessly approaching man. He tells us that the wily heast supplies the want of swiftness by the extraordinary degree of cuuning which it manifests in surprising its prey; he relates how it will climb a tree, and there lie in ambush for the elk and the rein-deer, pouncing on their backs as they pass unsuspiciously beneath, and adhering so firmly by its claws, that all efforts to dislodge the grim rider hy the tortured and terrified animal are vain. Nor is this all; it is said even to bait the ground by throwing down the moss which is so favourite a morsel with the reindeer, to lure that animal to its destruction. So much for legends. Turn we now to the accouuts of actual ohservers. Sir John Richardson remarks that this character of the Glutton seems to be entirely fictitious, and to have partly originated in the name of Glutton having been given occasionally to Lynxes and Sloths, adding, after recapitulating it, that it is very dissimilar to the habits of the American Wolverene.

Buffon's name of the 'Quadruped Vulture,' as applicahle to the Glutton, has more foundation in fact, for it appears to prey occasionally at least upon the dead bodies of quadrupeds; but so much cannot be said for his repetition of the assertion that the beast will approach man without fear—unless indeed it is sorely pressed by hunger.

Sir John Richardson states that the Wolverene feeds chiefly upon the carcasses of beasts which have been killed hy accident, that it has great strength, and that it annoys the natives hy destroying their hoards of provision, and demolishing their marten traps.

Mr. Graham in his manuscripts informs us that the Wolverenes are extremely mischievous, and that they do more damage to the small fur trade than all the other animals conjointly. They will, he states, follow the marten-hunter's path round a liue of traps extending 40, 50, or 60 miles, and render the whole unserviceable, merely to come at the baits, which are generally the head of a partridge or a bit of dried venison. They are not fond of the martens themselves, but never fail of tearing them in pieces or of burying them in the snow hy the side of the path, at a considerable distauce from the trap. Drifts of snow often conceal the repositories thus made of the martens at the expense of the hunter, in which case they furnish a regale for the hungry fox, whose sagacious nostril guides him unerringly to the spot; and two or three foxes are often seen following the Wolverene for this purpose.

Such is Mr. Graham's interestiug and, we helieve, faithful account of the habits of the Wolverene. May not the attendant foxes have given rise to the story that the arctic fox is the jackal, or provider of the Glutton?

Sir John Richardson says of the Glutton, "It is so suspicious, that it will rarely enter a trap itself, but hegiuning behind, pulls it to pieces, scatters the logs of which it is huilt, and then carries off the bait. It feeds also on meadow mice, marmots, and other rodeutia, and occasionally on disabled quadrupeds of a larger size. I have seen one chasing an Americau hare, which was at the same time harassed by a snowy owl. It resembles the bear in its gait, and is not fleet; hut it is very industrious, and no doubt feeds well, as it is generally fat. It is much abroad in the wiuter, and the track of its journey in a single night may be often traced for many miles. From the shortness of its legs, it makes its way througu loose snow with difficulty, but when it falls upon the beaten track of a marten-trapper, it will pursue it for a long way." ('Fauua Boreali-Americana.') The same author remarks that the Wolverene is said to bc a great destroyer of beavers, but that it must be only in summer, when those industrious animals are at work on laud that it can surprise them; for an attempt to break open their house in winter, even supposing it possible for the claws of a Wolverene to penetrate the thick mud-walls when frozen as hard as stone, would only have the effect of driving the beavers into the water to seek for shelter in their vaults on the borders of the dam. He further tells us that though the Wolverene is reported to defend itself with boldness and success against the attack of other quadrupeds, it flies from the face of man, and makes but a poor fight with a hunter, who requires no other arms than a stick to kill it.

Captain Sir James Ross (Appendix to Sir John Ross's 'Last Voyage') gives a striking narrative of the holdness of the species when urged by famiue. The incident happened at Victoria harbour. "There," writes the gallant captain, "in the middle of the winter, two or three months before we abandoned the ship, we were one day surprised hy a visit from one, which, pressed hard by hunger, had climbed the snow-wall that surrounded our vessel, and came boldly on deck, where our crew were walking for exercise. Undismayed at the presence of twelve or fourteen men, he seized upon a canister which had some meat in it, and was in so ravenous a state that whilst busily engaged at his feast he suffered me to pass a noose over his head, by which he was immediately secured and strangled. By discharging the contents of two secretory organs, it emitted a most iusupportable stench. These secretory vessels are about the size of a walnut, aud discharge a fluid of a yellowish-brown colour, and of the consistence of honey, by the rectum, when hard pressed by its enemies."

The Wolverene produces youug once a year, in numher from two to four, and the cubs are covered with a downy fur of a pale cream colour. (Richardson.)

It is found throughout the whole northeru parts of the American Continent, from the coast of Labrador and Davis's Straits to the shores of the Pacific and the islands of Alaska. It eveu visits the islands of the Polar Sea, its bones having been found in Melville Island, nearly in latitude 75°. It is not rare in Canada. The extent of range to the southward is not mentioned by American writers. (Richardson.)

Sir James Ross remarks that some traces of the existence of the Wolverene iu the highest northern latitudes were observed on two of the Arctic expeditions: but none of the animals were seeu on those occasions; although, he observes, we know that it remains throughout the wiuter as far uorth as 70° N. lat., and is not, like other auimals of that rigorous climate, subject to any change of colour from the intense cold. A few days previous to the arrival of the Esquimaux near Felix Harbour, in January 1830, the tracks of this auimal were first seeu; aud soon after the skins of two old and two young ones were hrought to the ship by the natives, who had taken them in traps huilt of stone. During each of the following wiuters their tracks were occasionally seen, and at Victoria Harbour they were very numerous.

Pennant notes it as iuhabiting Lapland, the northeru and eastern parts of Siberia, and Kamtschatka.

Lesson states that it inhabits a complete circle round the north pole, in Europe and Asia, as well as America.

We have seen what mischief the Glutton does to the trapper, and the skin of the animal does not compensate for its destructive habits. Pennant says that the skin sold in Siberia for four or six shillings; at Yakutsk for twelve shillings; and still dearer in Kamtschatka, where the women dress their hair with its white paws, which they reckon a great ornament. The fur, he adds, is greatly esteemed in Europe, and he remarks that the skins of the north of Europe and Asia, which are sometimes to be seen in the furriers' shops, are infinitely finer, blacker, and more glossy than those from America. Sir John Richardson says that the fur of the American Glutton bears a great similarity to that of the black bear, but that it is not so long nor of so much value.

The head of this animal is broad and compact, suddenly rounded off on every side to form the nose; jaws resembling those of a dog in shape; back arched; tail low and bushy; legs thick and short: whole aspect indicating strength without much activity. Fur generally dark-brown, passing in the height of winter almost into black. A pale reddish-brown band, more or less distinct, and sometimes fading into soiled brownish-white, commences behind the shoulder, and running along the flanks turns up on the hip and unites with its fellow on the rump; the short tail thickly covered with long black hair; some white markings, not constant in size or number, on the throat and between the fore legs; legs brownish-black; claws strong and sharp.

Sir John Richardson, from whose work ('Fauna Boreali-Americana') the above description is taken, adds that the animal places its feet on the ground much in the manner of a bear, and imprints a track on the snow or sand, which is often mistaken for that of the bear by Europeans on their first arrival in the Fur Countries; but the Indians distinguish the tracks at the first glance by the length of the steps. It has the following dimensions:—

	Feet.	Inches.
Length of head and body	2	6
Length of tail (vertebræ)	0	7
Length of tail with fur	0	10

The Grison, *Gulo vittatus* of Desmarest, *Viverra vittata* of Schreber and Gmelin, *Lutra vittata* of Traill, *Ursus Brasiliensis* of Thunberg, and *Galictis vittata* of Bell. The anatomy of this animal has been made known to us by Mr. Martin, who, in the 'Zoological Proceedings' for 1833, states the results of the post mortem examination of a male which had been kept in the Gardens at the Regent's Park. The animal, from the nose to the insertion of the tail, measured 1 foot 6 inches, and the tail was 6½ inches in length. The intestines, as in the *Mustelidæ* generally, exhibited no division into small and large, except that the rectum became gradually increased in circumference; their total length was 4 feet 5 inches. The stomach, when moderately inflated, measured 10½ inches in its greatest circumference, 13 along its greater, and 4 inches along its lesser curve. The omentum was thin and irregularly puckered together. At about 5 inches from the anus commenced a group of thickly crowded mucous follicles, occupying a space of 4 inches in length. The anus was furnished with two glands, each of the size of a nutmeg, and containing a fluid of the consistence and colour of liquid honey, and of a most intolerable odour: the orifice or duct of these glands opened just within the verge of the anus. The liver was tripartite, the middle portion being divided into one large and one small lobe; on the under side of the large lobe, in a deep furrow, was situated the gall-bladder, of a moderate size and somewhat elongated form. The biliary secretion entered the duodenum an inch and a half below the pylorus. The pancreas was long, flat, and narrow; beginning in a curved form near the pylorus, and following the course of the duodenum for about 4 inches. The spleen, tongue-shaped, was loosely attached to the stomach and 6 inches in length. The lungs consisted of three right and two left lobes. The heart was of an obtuse figure, measuring an inch and a half in length and an inch in breadth. The primary branches of the aorta were, 1st, a right branch, or arteria innominata, which, running for a quarter of an inch, gave off the two carotids and the right sub-clavian; and, 2nd, a left branch, passing to form the right subclavian. The epiglottis was acuminate, and in close approximation to the tongue, which was tolerably smooth, with a crescent of distinct fossulate papillæ at its base. The os hyoides was united by a succession of four bones on each side to the skull. The kidneys were of an oval form, the right being half its length higher than the left; length of each an inch and a half. The tubuli entered the pelvis of the kidney by a single large conical papilla. Supra-renal glands small. The testes each as large as a small nutmeg; the cremaster muscle, embracing the spermatic cord as it emerges from the ring, very distinct. The penis had been injured in removing the skin of the animal; its length from the pubes was about 3½ inches, and its muscles were very distinct. It contained, as in the dog, a slender bone, 1¾ inch long, rather stout at its commencement, then narrowing as it proceeded till near the apex, when it suddenly bent at an obtuse angle, giving off at this part two small processes. The distance of the prostate from the bladder was an inch and a half.

The habits of the Grison are very sanguinary, and it is a great destroyer of the smaller quadrupeds. It inhabits the greater part of South America, but more particularly Guyana and Paraguay. Dr. Rengger notes both it and *Gulo barbarus* among the plantigrade *Carnivora* of Paraguay, where both species are called Yaguape.

The head is rather large; ears broad and short. Body very much elongated; fur above deep brown, each hair tipped with white, which gives a gray or hoary aspect to the upper parts. A broad white line passing on each side of the front to the shoulders. Nose, throat, underside of body, thighs, and legs, black. Length about 2 feet.

Grison (*Gulo vittatus*).

There is a notice in the 'Zoological Proceedings' for 1830-31 of the exhibition of a living quadruped referrible to *Gulo barbarus*. It was presented to the Society by Edmonstone Hodgkinson, Esq., of Trinidad, who described it as being "playful and gentle, although easily excited and very voracious. It is exceedingly strong, as is indicated by its shape; and it has the same antipathy to water as a cat." Mr. Hodgkinson suspected it to be a native of Peru. He obtained it in Venezuela, where it was presented to him by the president, General Paez. The name he received with it was the Guache; but this appellation, it was observed by Mr. Bennett, was probably erroneously applied to the present animal, belonging rather to the Coati, the orthography of which is variously given as Coati, Couati, Quasje, Quachi, and Guachi. The latter form, it is remarked, occurs in the 'Personal Narrative' of the Baron Von Humboldt, where it evidently refers to a nocturnal species of *Nasua*. The form and general appearance of the animal were remarked to be altogether those of a *Mustela*, to which genus, it was observed, it should probably be referred, together with the typical *Gulo barbarus*. A specimen of the latter was placed upon the table, from which the living animal was shown to differ by the absence of the large yellow spot beneath the neck: a remarkable distinction in this group, but on the occurrence of which, unless confirmed by several specimens, it was considered improper to propose regarding it as a distinct species.

There is a figure and description of the *Galera*, referred to by Linnæus for his *Mustela barbara*, in Browne's 'Jamaica,' p. 485, tab. 49. Browne calls it the *Galera*, or Guinea Fox, and says that it is often brought to Jamaica from the coasts of Guinea (Guyana?), where it is a native, and frequent enough about all the negro settlements. It is, he says, of the size of a small rabbit or cat, and very strong in its fore feet, which are much shorter than the hinder. [MUSTELIDÆ.]

Fossil Gluttons have been detected in the ossiferous caverns; *Gulo spelæus* (Goldfuss), for instance, has been found in those of Gailenreuth, and Sundwick, in Westphalia. Professor Kaup also records another extinct species, *Gulo antediluvianus* (Kaup), from the Epplesheim Sand.

GUM, a vegetable substance frequently met with in the tissues of plants. It exudes from some plants in large quantities, especially the species of *Acacia* [ACACIA], and is collected for commercial and medicinal purposes. [GUM, in ARTS AND SC. DIV.] In a pure state gum is clear, and when dry it is brittle like glass. It is soluble in water and dilute acids, but not so in ether, alcohol, and volatile and fixed oils. The action of alcohol makes it horny, and it is coloured pale yellow by iodine. Its composition is nearly identical with starch and dextrine. Berzelius makes it C_{12} H_{11} O_{11}, and Mülder C_{12} H_{10} O_{10}. It closely resembles dextrine, and through it is allied to starch. The substances called Cerasin, Arabin, and Vegetable Mucilage, seem to be modifications of gum. The principal difference between gum and dextrine consists in the fact that by the action of dilute sulphuric acid, or diastase, the latter is converted into grape-sugar, which is not the case with gum. Gum seems to originate with dextrine. [DEXTRINE; STARCH.]

GUM-RESINS are substances found in plants in which Gum and Resin are mixed together in various proportions. Some families of plants, as the *Umbelliferæ*, are remarkable for exuding these substances. Ammoniacum, Assafœtida, Sagapenum, and Galbanum, are examples. They frequently contain mixed with them a volatile oil which gives to them a medicinal value. [GUM-RESINS, in ARTS AND Sc. DIV.]

GUM-TRAGACANTH. [ASTRAGALUS.]

GUM-TREE. [EUCALYPTUS.]

GUMS. [DENTITION; TEETH.]

GUNNELL. [MURÆNIDÆ.]

GURHOFFIAN. [DOLOMITE.]

GURNARD. [TRIGLA.]

GUTTIFERÆ. [CLUSIACEÆ.]

GUYAQUILLITE, a form of Fossil Resin found in South America. It is soluble in alcohol.

GYALL, the name of the Indian Jungle Bull, *Bos frontalis* of Lambert. [BOVIDÆ.]

GYMNADE'NIA, a genus of Plants belonging to the natural order *Orchidaceæ* and the tribe *Ophrydineæ*. It is distinguished from the genus *Orchis* by the glands of the pollen masses being without a pouch. There are two British species, *G. conopsea* and *G. albida*.

G. conopsea has a 3-lobed lip; the lobes equal, entire, obtuse; the lateral sepals spreading, spur filiform, twice as long as the germen; root-knobs, palmate. The stem is a foot high; leaves linear-lanceolate.

G. Breyerii is a native of South America at the river Magdalena. It has blue flowers; leaves with two or three pairs of unequal leaflets, the extremo ones oblong, elliptical, unequal-sided, middle pair obovate, lower ones roundish; peduncles umbellate.

G. verticale is a native of Mexico and St. Domingo. The flowers are blue with vertical petals. The leaves with three or six pairs, but usually five pairs of oblong coriaceous mucronate leaflets, the outer ones obovate, which are as well as the branches very smooth.

G. sanctum is a tree 20 feet high, a native of South America, particularly in the island of St. Domingo, Mexico, and Brazil.

GYMNARCHUS, a genus of Malacopterygious Apodal Fishes. The body is long and scaly; the gill opening before the pectoral fins; dorsal fin running the whole length of the back; tail ending in a point; head naked and conical; mouth small, with a single row of cutting teeth. *G. Niloticus* is the only species; it inhabits the Nile.

GYMNEMA, a genus of Plants belonging to the natural order *Asclepiadaceæ*. It has a sub-urceolate 5-cleft corolla, the throat usually crowned by five scales or teeth inserted in the recesses between the segments of the corolla. The stamineous corona is wanting. The anthers terminate by a membrane, the pollen masses are erect, fixed by the base. The follicles smooth. Seeds comose, generally marginate. The species are usually twining shrubs, natives of the East Indies, the tropical parts of Australia, and Equinoctial Africa. The leaves are opposite, membranous, and flat. The umbels interpetiolar and cymose. In the greater number of species the stamens are not usually naked, but are furnished with a gland-like body or fleshy tuft at the base of each filament.

G. lactiferum, Cow-Plant, or Milk-Bearing Gymnema, has an erect stem, or rather twining; the leaves are on short petioles, ovate, bluntly acuminated, usually unequal-sided; the umbels many-flowered, shorter than the petioles; the throat of the corolla crowned by five fleshy tubercles; the tube furnished with double pilose lines running from the tubercles. It is a native of Ceylon, where the milk of the plant is sometimes substituted for cow's milk, and the leaves are boiled with food.

G. tingens is a native of Pegu. It has a twining glabrous stem, cordate leaves, acuminated to oval; the umbels or corymbs often twiu, at first shorter than the petioles, and at length spirally elongated; the glands of the filaments one-half shorter than the stamens; follicles cylindrical, spoon-shaped; stigma simple, oval, mutic, crowning the tube of the corolla, and therefore exceeding the stamens. The flowers are largish, numerous, and of a pale-yellow colour. The calyx 5-cleft to the base. From the leaves of this plant a green dye is prepared by the Burmese. Seventeen species of this genus are enumerated, none of them of any particular interest.

(Lindley, *Vegetable Kingdom;* Don, *Dichlamydeous Plants.*)

GYMNETRUS, a genus of Fishes belonging to the group of Riband-Shaped *Acanthopterygii*. It has the following characters:—Body elongated, compressed; a single dorsal fin extending the whole length of the back; ventrals consisting each of a single ray, only sometimes very long and dilated at the end; no anal fin; teeth pointed, small. The species of this genus have very rarely been obtained entire. They have generally been taken dead, and consequently have been crushed and mutilated. Of the species of this genus, Mr. Yarrell says, "three probably belong to the Mediterranean, two to the seas of the North of Europe, and two to India. One northern species, besides one of those apparently belonging to India, has been taken on the shores of this country. That of the north has occurred more than once in Scotland; that of India once on the coast of Cornwall."

G. Hawkenii (Bloch), Hawken's Gymnetrus, the Oared Gymnetrus, the Ceil Conin of Cornwall. This species has been taken in Cornwall. The following description has been drawn up by Mr. Couch from a drawing and notes of a specimen taken in a net at Mount's Bay in 1791:—"The length without the extremity of the tail, which was wanting, was 8½ feet; the depth 10¼ inches; thickness 2¾ inches; weight 40 lbs. In the drawing the head ends in a short and elevated front; eye large; pectoral fin round; no anal fin; the dorsal fin reaches from above the eye to the tail. The ventrals are formed of four long red processes, proceeding from the thorax, and ending in a fan-shaped appendage, of which the base is purple, the expansion crimson. The back and belly are dusky-green; the sides whitish; the whole varied with clouds and spots of a darker green; the fins crimson." A very fine specimen of this fish caught off the coast of Northumberland, was exhibited in London at the time the discovery of the Great Sea-Serpent was announced, and was supposed to explain the nature of this discovery.

The *Gymnetrus arcticus* of Cuvier, the Vaagnaer, or Deal-Fish, has been referred to the genus *Trachypterus*. [TRACHYPTERUS.]

GYMNOCEPHALUS. [CORACINA.]

GYMNO'CLADUS (from γύμνος, naked, and κλάδος, a branch), a genus of Plants belonging to the natural order *Leguminosæ*. It has diœcious flowers; the calyx tubular, 5-cleft; the petals five, equal, oblong, exserted from the tube; the stamens ten, inclosed; the legume oblong, thick, filled with pulp inside. There is but one species, *G. Canadensis*, the Kentucky Coffee-Tree. It is an upright deciduous tree, with compound alternate, stipulate, bipinnate leaves, and white flowers in terminal racemes. The branches of this tree are without any appearance of buds, which, during the winter, gives it the aspect of a dead tree, and hence the Canadian name 'chicot,' or stump-tree. The wood is hard, compact, and of a fine rose colour. In America it is used in cabinet-making and carpentry. It has the property of rapidly converting its sap-wood into heart-wood, so that the smallest trees may be converted to useful purposes. The seeds were at one time roasted and ground as a substitute for coffee in Kentucky and Tennessee; but they are not often used in this way at the present day. The pods, preserved in the same way as the tamarind, are said to be wholesome and aperient. This tree grows well in Great Britain, but does not ripen its seeds. It is best propagated by imported seeds, but it will also grow freely from cuttings of the roots. It requires a rich, deep, free soil. (Loudon, *Encyclopædia of Trees and Shrubs.*)

GYMNODACTYLUS. [GECKOTIDÆ.]

GYMNODERUS. [CORACINA.]

GYMNOGASTER. [TRACHYPTERUS.]

GYMNOGENS, or GYMNOSPERMS, one of the divisions under which the vegetable kingdom is now classified. The name is derived from the seeds being naked, that is to say, unprotected by a pericarpal covering, and fertilised by the pollen coming in direct contact with the ovule, not by the intervention of the apparatus called stigma and style. In this respect Gymnosperms are analogous to those reptiles which, in the animal kingdom, have eggs that are impregnated by the male after they have been deposited by the mother.

The plants comprehended in this class have nearly an equal relation to flowering and flowerless plants. With the former they agree in habits, in the presence of sexes, and in their vascular tissue being complete; with Ferns and Club-Mosses, among the latter, some also accord in habit, in the peculiar gyrate vernation of the leaves of some Cycads, in their spiral vessels being imperfectly formed, and in the sexes being less complete than in other flowering plants; the females wanting a pericarpal covering, and receiving fertilisation directly through the foramen of the ovule, without the intervention of style or stigma, and the males sometimes consisting of leaves imperfectly contracted into an anther bearing a number of pollen-cases upon their surface. So great is the resemblance between Club-Mosses and certain Conifers, that there is no obvious external character except size by which they can be distinguished. Gymnogens are known from most other *Vasculares* by the vessels of their wood having large apparent perforations or discs. [CONIFERÆ.] It is not however on this account to be understood that they differ in growth from other Exogens; on the contrary they are essentially the same, deviating in no respect from the plan upon which Exogenous Plants increase, but having a kind of tissue peculiar to themselves. At this point of the vegetable kingdom there is a plain transition from the highest form of organisation to the lowest. Gymnogens are essentially Exogens in all that appertains to the organs of vegetation; they have concentric zones in their wood, a vascular system in which spiral vessels are found, and a central pith, but they are analogous to reptiles in the animal kingdom. The two most remarkable of the orders are Conifers and Cycads. Of these the former is connected with Club-Mosses among Acrogens by means of the extinct genus *Lepidodendron*, and their branches are sometimes so similar to those of certain Lycopods themselves as to leave no doubt of their relation. Compare, for instance, *Lycopodium phlegmaria*, and *Cunninghamia sinensis*. Some Cycads have the gyrate vernation of the leaves of true Ferns, along with the inflorescence of Conifers; and their mode of forming their trunk, although essentially the same as that of Exogens, yet resembles the growth of Acrogens in lengthening by a terminal bud only. While however the class of Gymnogens is thus distinctly marked by the most important physiological peculiarities, it approaches the highest forms of vegetation by that portion of it which bears the name of Joint-Firs (*Gnetaceæ*)—plants with all the structure of their class, but with the manner of growth of Chloranths (*Chloranthaceæ*) and Beefwoods (*Casuarinaceæ*). (Lindley 'Vegetable Kingdom.')

The following figure of *Juniperus Oxycedrus* will show the peculiarities of this class:—*Fig.* 1 is a male catkin; *fig.* 2, a scale from it having anthers on its under side; *fig.* 3, a female cluster of flowers seated at the end of a scaly peduncle; *fig.* 4, a longitudinal section of the same, showing the naked ovules seated within the scales; *fig.* 5 is a ripe fruit, composed of three scales, become fleshy and consolidated, and burying the seeds within their centre; *fig.* 6 is the same fruit divided transversely, to show how the seeds are placed within the ripe fruit; *fig.* 7 is a seed; *fig.* 8, a longitudinal, and *fig.* 9, a transverse section of the same. [CYCADACEÆ; TAXACEÆ; GNETACEÆ; CONIFERÆ.]

Juniperus Oxycedrus.

GYMNOPS, a genus of Birds established by Cuvier and described by him as having a bill strong as that of the Orioles; the nostrils round, without scales or any membranous entourage, and a great part of the head denuded of feathers. He refers to *Gracula calva*, Gmel., *Mino Dumontii*, Less., and *Gracula cyanotis*, Lath. (*Merops cyanotis*, Sh.), as examples.

GYMNOSPERMS. [GYMNOGENS.]

GYMNO'TUS, a genus of Fishes belonging to the section *Apodes*. It has the following generic characters:—Gills partially closed by a membrane, and opening before the pectorals; the vent placed very far forwards; body without any perceptible scales, and without dorsal fin; anal fin extending the greater part of the length of the body.

G. electricus (Linn.), from the resemblance it bears to an eel, and the electric power which it possesses, has been called the Electric-Eel. It is about 5 or 6 feet in length; the head is rather broad and depressed; the muzzle is obtuse: the body, compared with that of the common eel, is stouter and shorter in proportion; the anterior part is nearly cylindrical, but towards and at the tail it is compressed; the pectoral fins are small and rounded; the anal fin commences at a short distance behind the line of the pectoral fins, and extends uninterruptedly to the tail; there is no caudal fin. Its colour is brownish-black.

The Electric-Eel is said to communicate shocks so violent that men and even horses are overpowered by them. This power is dependent on the will of the animal, but decreases in strength if frequently repeated, unless at considerable intervals. The organs by which this shock is produced are minutely described by Hunter in the 65th volume of the 'Philosophical Transactions.' All the species of *Gymnotus* inhabit the rivers of South America. [ELECTRICITY OF ORGANIC BEINGS.]

The genus *Carapus* of Cuvier contains such species of *Gymnotus* of the older authors as have the tail lengthened and tapering, and the body compressed and furnished with scales. They also inhabit South America.

GYMNU'RA, a genus of Animals belonging to the family *Talpidæ* and the order *Feræ* of Dr. Gray. The only species of this genus was first described by Sir Stamford Raffles. It was afterwards more accurately examined by Dr. Horsfield and Mr. Vigors, who figured it in the 'Zoological Journal.'

Sir Stamford Raffles referred the species to the Linnæan genus *Viverra*, and recorded it as *Viverra Gymnura*. But although he did not nominally raise the animal to the importance of a genus, he gave so clear and accurate a description of its generic characters that Dr. Horsfield and Mr. Vigors do not hesitate to attribute the first indication of the group to him; and they proceed to give the generic character of *Gymnura*:—

$$\text{Incisors, } \frac{2}{6}\text{; canines (}\textit{Laniarii}\text{), } \frac{2-2}{1-1}\text{; molars, } \frac{8-8}{7-7} = 44.$$

Incisors, 2 above, remote, very large, subcylindrical, rounded at the apex; 6 below, the four intermediate approximate, rather short, inclined (proclives) compressed, the anterior surface (pagina) convex, the interior flat, edge rounded (scalpro rotundato), the two lateral abbreviated, acute. Canines (Laniarii), 2 on each side above, remote from the incisors and shorter than them, the anterior ones the longest; 1 on each side below, very large, conical, subarcuate, looking inwards. Molars, 8 on each side above, remote from the canines, the three anterior unicuspid, the first elongated and sectorial; the second and third abbreviated; the fourth with an elongated conical point and a posterior and exterior abbreviated lobe or step (gradu) at the base; the fifth with the exterior cusp very long, and the interior one abbreviated; the sixth and seventh very large, multicuspid, the cusps sub-abbreviated and rounded; the eighth smaller and more fashioned for triturating (subtritorius), the cusps rather obtuse; 7 below, the three anterior unicuspid, compressed; the first and second shorter; the third sub-elongated; the fourth with an elongated cusp, an anterior lobe, and another posterior lobe (gradu) abbreviated; the fifth, sixth, and seventh very large, multicuspid, the cusps rather elevated and acute.

Head elongated, acuminated, narrowed, compressed on the sides, flattish above. Muzzle (rostrum) obtuse, elongated, stretched forward (protensum), much surpassing the lower jaw in length. Nostrils lateral, prominent, with the margins convoluted. Tongue rather smooth, large. Auricles rounded, somewhat prominent, naked. Eyes small. Whiskers (vibrissæ) elongated.

Body rather robust, ground of the fur (cordaris) soft, but with distant erect sub-elongated harsh hairs. Tail rather long, smooth, attenuated, naked, scaly, with a few scattered hairs in youth.

Feet moderate, plantigrade, pentadactyle, the fore feet with a rather short thumb, the three intermediate fingers rather long and sub-equal; the hind feet with a very short great toe, the three intermediate toes very much elongated, and the external toe moderate. Claws moderate, narrow, curved, compressed, very acute, retractile.

Such is the character given by Dr. Horsfield and Mr. Vigors to *Gymnura*, and they state their opinion that the nearest affinity to this genus appears to be met with in *Tupaia* (Raffles). From that group however they say that *Gymnura* is sufficiently distinguished, besides the difference in the system of dentition, by the elongation of the rostrum, the comparative robustness of the body, the setose character of the hairs, which are sparingly mingled with the soft fur, the small retractile claws, and the nakedness of the tail. In general appearance they hold that the group bears a strong resemblance to some species of the Marsupial genus *Didelphis*.

G. Rafflesii, the Bulau or Tikus, has the body, feet, stripe above the eyes, scattered occipital hairs, and the basal half of the tail, black; the head, the neck, the scattered hairs of the back, and the other half of the tail, white. (Horsfield and Vigors.)

An adult specimen examined by Horsfield and Vigors measured—

	Ft.	In.	Lines.
Length of the body and head from the extremity of the proboscis to the root of the tail	1	2	3
Length of the tail	0	10	6
Length of the head	0	4	3
Length of the proboscis	0	0	8
Breadth of the head across the ears	0	1	6
Distance between the eyes	0	1	0
Height at the shoulder	0	5	0
Height at the rump	0	4	6
Length of the anterior tarsus and toes	0	1	9
Length of the posterior ditto	0	2	0

M. Lesson ('Manual,' 1827), places the 94th genus, *Gymnura*, between the dogs with hyæna's feet (*Canis pictus*, Desm.; *Hyæna picta*, Temm.), and *Viverra*, Linn., the first sub-genus of which he makes to consist of the true Civets. He says of *Gymnura*, "We form this genus in conformity with the opinion (d'après l'avis) of M. Desmarest, in order to place in it an animal closely approximating to the Civets, and perhaps approximating still nearer to the *Paradoxuri*, which are plantigrade. We place it provisionally among the digitigrades. It has a pointed muzzle, a soft tongue, rounded ears, erect and naked, compressed claws, curved and sharp, a naked tail, and the following dental formula:—

"Incisives, $\frac{6}{6}$; canines, $\frac{1-1}{1-1}$; molars, $\frac{6-6}{6-6}=40$.

"In the upper jaw the two middle incisives are the largest, and separated (écartées) one from the other; the two lateral ones are very small; the canines are moderate. The first molar has two points, the second one only; the fourth and fifth have four tubercles, the sixth has only three.

"In the lower jaw the canines are long.

"Species, *Gymnura Rafflesii*, *Viverra Gymnura*, Raffles. This species, from the East Indies, has the muzzle, which exceeds the lower jaw by an inch, pointed; the eyes are small, the moustaches long; the tail, which is naked, like that of a rat, is only 10 inches long, and the head and body measure 1 foot. The fur consists of two sorts of hair, a short under fur (bourre) very thick and soft, and a long harsh hair; the body, legs, and first half of the tail are black; the head, the neck, and the shoulders are white; a black band passes over the eyes. Habits unknown."

Gymnura Rafflesii. Horsfield and Vigors.

M. Lesson does not state from what specimen he has taken his descriptions, which vary from those of Dr. Horsfield and Mr. Vigors, in some instances essentially; but the latter state the ample materials from which they defined their characters.

Cuvier says, "The genus *Gymnura* of Messrs. Vigors and Horsfield 'Zool. Journal,' iii. pl. 8) appears to approach *Cladobates* in its teeth, and the shrews (musaraignes) in its pointed muzzle and scaly tail. It has five unguiculated toes on all its feet, and rather stiff bristles (soies assez rudes) projecting forth from the woolly hair. It cannot be well classed till its anatomy is known."

The term *Gymnura* has been applied to designate a genus of Sea-Ducks [DUCKS]; and Spix uses the word *Gymnuri* as the name of a family of South American Monkeys.

GYNA'NDRIA, one of the classes in the artificial system of botany invented by Linnæus, the character of which is to have the stamens and pistil consolidated into a single body. The principal part of the class consists of Orchidaceous Plants, forming in it the order *Monandria*.

GYNOCARDIA. [FLACOURTIACEÆ.]

GYPAËTOS, Storr's generic name for the Lämmergeyer, or Bearded Griffin (*Gypaëtos barbatus*), a bird of prey which may be considered as intermediate between the Eagles and the Vultures. [VULTURIDÆ.]

GYPOGE'RANUS (Illiger), a genus of Birds embracing the well-known Secretary Bird. Mr. Bennett, in the 'Tower Menagerie,' remarks that the singular conformation of this bird, so different in many respects from that of the order to which both in its leading characters and in its habits it obviously belongs, rendered it for a long time the torment of ornithologists, who puzzled themselves in vain to assign it a definite place in the system, and could not agree even with regard to the grand division of the class to which it ought to be referred. "Thus" continues the author, "M. Temminck was at one time inclined to refer it to the Gallinaceous order; and M. Vieillot, after repeatedly changing his mind upon the subject, at last arranged it among the Waders, with which it has absolutely nothing in common except the length of its legs. It appears however to be now almost universally admitted that its closest affinity is with the Vultures, with which it agrees in the most essential particulars of its organisation, and from which it differs chiefly in certain external characters alone, which unquestionably give to it an aspect exceedingly distinct, but are not of themselves of sufficient importance to authorise its removal to a distant part of the classification. It constitutes in fact one of those mixed and aberrant forms by means of which the arbitrary divisions of natural objects established by man are so frequently assimilated to each other in the most beautiful, and occasionally in the most unexpected manner." Mr. Swainson, in the first volume of his 'Classification of Birds,' places the "Secretary Vulture of Africa" among the *Vulturidæ*; but in the second volume of the same work (1837), he makes it a genus of the *Aquilinæ*, a subfamily of the *Falconidæ*.

Dr. Sparrman first saw this bird (a drawing of which, given by M. Vosmaer under the denomination of *Sagittarius*, he alludes to) in the neighbourhood of the warm baths of Hottentot Holland. "It is not," he says, "a very shy bird, but when scared begins at first to endeavour to save itself by alternately hopping and scudding along very swiftly, and afterwards does it more effectually by flight. In external appearance, in some respects it resembles the eagle, and in others the crane, two birds certainly very unlike each other; though in my opinion it ought to be referred to neither of these genera. The Hottentots give it a name most suitable to its nature, namely, as translated into Dutch, Slangen-Vreeter (or Serpent-Eater); and in fact it is for the purpose of confining within due bounds the race of serpents, which in Africa is very extensive, that nature has principally destined this bird. It is larger than our crane, with legs 2½ feet long, and the body in proportion less than the crane's. Its beak, claws, stout thighs covered with feathers, and short neck, are like those of the eagle and hawk kind." Then follows a particular description of the bird, after which the Doctor continues thus: "This bird has a peculiar method of seizing upon serpents. When it approaches them it always takes care to hold the point of one of its wings before it, in order to parry off their venomous bites; sometimes it finds an opportunity of spurning and treading upon its antagonist, or else of taking it up on its pinions and throwing it into the air; when by this method of proceeding it has at length wearied out its adversary, and rendered it almost senseless, it then kills it and swallows it without danger. Though I have very frequently seen the Secretary Bird, both in its wild and tame state, yet I have never had an opportunity of seeing this method it has of catching serpents; however I can by no means harbour any doubt concerning it, after having had it confirmed to me by so many Hottentots as well as Christians; and since this bird has been observed at the menagerie at the Hague to amuse and exercise itself in the same manner with a straw. If, finally, this serpent-eater is to be referred to the *Accipitres*, or the Hawk kind, the name of *Falco Serpentarius* appears to be the most proper to distinguish it by in the 'Systema Naturæ.' It has even been remarked that these birds, when tame, will not disdain now and then to put up with a nice chicken."

Sparrman, it is true, did not himself see the scene which he describes; but that his account is correct in the main will not be doubted when we present the reader with a translation of the testimony of an eye-witness—of one at whose relations the devoted admirers of Buffon were too apt to smile incredulously, but whose accuracy is now generally allowed to be unimpeachable. We give it entire, because even in those parts which are not directly illustrative of the habits of the bird, the difference between the actual observer, the field zoologist, who had studied nature in her own wilderness, and the cabinet theorist, who had only viewed her through the false medium of his own brilliant but delusive imagination, is strikingly displayed. Le Vaillant, in one of his journeys in the Namaqua country, arrived at a spring at the very moment when a Secretary was drinking there: he killed it at the first shot, and gave to the well the name of the Secretary's Fountain. His narrative then proceeds as follows:—

"The Dutch have named this bird the Secretary on account of the tuft of plumes which it carries at the back of the head; for, in Holland, clerks (gens de cabinet), when they are interrupted in their writing, stick the pen among their hair behind the right ear, so as to imitate in some degree its crest. Buffon, speaking of it, says that it has only been known at the Cape recently; and the proof which he adduces is, that Kolbe and other succeeding writers say nothing of it. This is advancing a groundless assertion (un fait faux), and endeavouring to prove it by another as true as the first. The Secretary is known in the colonies both under the name of Secretaris and that of Slang-Vreeter. It is under this last denomination that Kolbe speaks of it; and he certainly knew it, at least from the relation of others, because he exactly enumerates all the kinds of food which it habitually takes. It is true that, in his description, he translates the Dutch word Slang-Vreeter by the French word Pélican, and that consequently he makes a single species out of two very different ones. But Kolbe was no naturalist, and his work contains so many other errors that it would be astonishing not to find this. I have been more surprised, I confess, to see that our modern naturalists, even those who have spoken of the Secretary in the greatest detail, make no mention of three bony and blunt protuberances which it has at the bend and last joint of the wings, but infinitely less apparent than in the Jacana or in the Kamicki. This omission has appeared strange to me, in Buffon particularly, who has not described it from the relation of others, but from an individual which he had before his eyes, and which I believe was in the cabinet of Mauduit. It is nevertheless an essential omission, because it deprives the Secretary of one of its principal distinctive characters, and because the protuberances of which I speak form one of the arms of the bird, as I shall presently show. I shall permit myself moreover to make a remark on what Buffon has written. According to him the Secretary differs from other birds in its timid nature; and its timidity is even such, says he, that when attacked by its enemies it has no other resource for its preservation excepting flight. This is an error. Those who have been able to study this bird know that, living especially on reptiles, it is continually at war with them; that it seeks them everywhere, and attacks them courageously. For this assertion I cite the testimony of Querhoeut, and bring forward in proof of it the fact which I have witnessed.

"In descending from a mountain into a very deep bog (fondrière) I perceived, nearly perpendicularly below me, a bird which raised and lowered itself very rapidly, with very extraordinary motions. Although I well knew the Secretary, and had killed many of these birds at Natal, it was impossible for me to recognise it in the vertical situation in which I found myself, and I only suspected that it was one from its bearing. Having found means, by favour of some rocks, to approach sufficiently near, noiselessly and without being discovered, I found that this bird was a Secretary combating a serpent. The fight was very sharp on both sides, and the skill (la ruse) equal on the part of each of the combatants. But the serpent, which perceived the inequality of its strength, employed that adroit cunning which is attributed to it, in order to save itself by flight and regain its hole; while the bird, divining its intention, stopped it at once, and throwing itself before the serpent by one spring cut off its retreat. Wherever the reptile essayed to escape there it always found its enemy. Then, uniting skill with courage, it erected itself fiercely to intimidate the bird, and presented, with a frightful hiss, a menacing gape, inflamed eyes, and a head swollen with rage and poison.

"Sometimes this offensive resistance suspended hostilities for an instant; but the bird soon returned to the charge; and covering its body with one of its wings as with a shield, struck its enemy with the other, with the bony protuberances of which I have already spoken, and which, like small clubs, overpowered it the more surely, inasmuch as it presented itself to the blows. In effect, I saw it reel and fall extended: then the conqueror threw himself upon it to finish his work; and with one blow of the bill split its skull.

"At this moment, having no further observations to make, I killed it. I found in its crop (for it has one, which nobody has stated), on dissecting it, eleven rather large lizards, three serpents as long as one's arm, eleven small tortoises very entire, many of which were about two inches in diameter, and, finally, a quantity of locusts (sauterelles) and insects, the greater part of which were sufficiently whole to deserve being collected and to be added to my specimens. The lizards, the serpents, and the tortoises had all received the stroke of the bill on the head. I observed besides, that independently of this mass of aliments the craw (poche) of the animal contained a species of pellet, as large as a goose's egg, and formed of the vertebræ of serpents and lizards which the bird had devoured previously, scales of small tortoises, and the wings, feet, and corselets of different *Scarabæi*. Doubtless when the undigested mass is become too large, the Secretary, like other birds of prey, vomits it and gets rid of it. It results from the superabundant quantity of nourishment which this specimen had secured, that in attacking the serpent of the bog, it was not hunger which had stimulated it to the combat, but the hatred and antipathy which it bears to these reptiles. Such an aversion as this is of an inappreciable advantage in a country where the temperature wonderfully favours the multiplication of an infinity of noxious and venomous animals. In this point of view the Secretary is one of nature's real benefactions; and indeed its utility and the services rendered by it are so well recognised at the Cape and in its neighbourhood, that the colonists and Hottentots respect it and do not kill it; herein imitating the Dutch, who do not kill the stork, and the Egyptians, who never injure the ibis.

"The Secretary is easily tamed, and when domesticated, every kind of nourishment, cooked or raw, agrees with it equally. If care be taken to feed it well, it not only lives amicably and peaceably with the poultry, but when it sees any dispute going on it runs to separate the combatants and to restore order. It is true that if it be permitted to suffer from hunger, it provides for itself, and then falls without scruple upon the ducklings and chicks. But this abuse of confidence, if abuse of confidence it can be called, is nothing but the imperious effect of want, and the pure and simple exercise of that necessity which devotes the half of all that breathes to the appetite of the other half. I have seen tame Secretaries at many houses. The eggs ordinarily amount to from two to three, nearly as large as those of a goose, and white like those of a hen. The young remain a long time before they quit the nest, because their legs being long and slender, they sustain themselves with difficulty. They may be observed, even up to the age of four months, unable to progress except by leaning on their heels; which gives them a strikingly clumsy and ungraceful air. Nevertheless, as their toes are not so long nor their claws so curved as the other birds of prey, they walk with much more facility than those. So that when they have attained the age of seven months they may be seen to develop easy and graceful movements which suit well with their noble bearing. Buffon, quoting the Dutch naturalist, says, that when the latter was drawing his Secretary, the curious bird came to look upon the paper with outstretched neck and upstanding crest, as if admiring its likeness, &c. Certainly the Secretary is sufficiently interesting on account of its instinct and natural qualities, without requiring to be gifted by its historian with an admiring taste for drawing and a sort of pride at seeing itself represented. If Vosmaer's Secretary approached him, stretching out its neck and raising its crest, it was, in my opinion, neither from curiosity nor delight, but only from a sort of habit which is common to many other birds. We know that the majority of them, when they are familiar and domesticated, love to have their polls scratched; that this titillation seems to give them pleasure; and that they present themselves to the first comer and stretch out their neck to beg for this service. We see this in Europe with reference to the peacock and the parrakeet.

"The Secretary is found on all the arid plains in the neighbourhood of the Cape. I have found it in the east, on the whole line of coast, in Caffraria, and even far inland. But in the west, although this part of Africa presents deserts still more arid than those of the east, and although it consequently offers to the bird the different sorts of food which are congenial to it, I have never met with one beyond the country of the Great Namaquas. I will add only one word on this interesting animal: it has not the bill of a gallinaceous bird, as Vosmaer says it has; but a true bill of a bird of prey. Nor has it, as Buffon declares, the leg bare of feathers like the shore birds (oiseaux de rivage). For the rest, I refer to my 'Ornithology,' where I shall enter into greater details on the subject of the Secretary." (Le Vaillant, 'Second Voyage dans l'Intérieur de l'Afrique,' &c., tom. ii.)

M. Lesson quotes the account of Mr. Smith, who relates that one day he saw a Secretary take two or three turns on the wing at a little distance from the place where he was. The bird soon settled, and Mr. Smith saw that it was attentively examining an object near the spot where it had descended. After approaching it with great precaution the Secretary extended one of its wings, which the bird continually agitated. Mr. Smith then discovered a large serpent raising its head, and appearing to wait the approach of the bird to dart upon it; but a quick blow of the wing soon laid it prostrate. The bird appeared to wait for the serpent's raising itself, in order to repeat the blow; but this the serpent, it seems, did not attempt, and the Secretary walking towards it, seized it with the feet and bill, and rose perpendicularly into the air, whence the bird let the serpent fall on the ground, so that it might be securely destroyed.

Gmelin placed the Secretary at the head of the genus *Falco*, immediately after the genus *Vultur*.

Duméril, Temminck, De Blainville, Latreille, Vigors, and Illiger place it in the order of Rapacious Birds.

Baron Cuvier arranges the form among the Falcons.

M. Vieillot places it among the *Grallatores*.

M. Lesson makes the third and last family of his Diurnal Birds of Prey consist of *Gypogeranus*; the first consists of the *Vulturidæ*, and the second of the *Falconidæ*.

Mr. Swainson makes the Secretary the third and last type of the family *Vulturidæ*.

Mr. Ogilby, at a meeting of the Zoological Society of London (July, 1835), observed that a Secretary (*Gypogeranus*) in Mr. Rendall's collection offered some peculiarities when compared with the common Cape animal, which at first induced Mr. Ogilby to believe that it might be a distinct species, and in this opinion he was in some degree confirmed by Mr. Gould; but he stated that a more attentive comparison of specimens from both localities (Mr. Rendall's having been sent from the Gambia), had considerably shaken his original opinion. Mr. Ogilby remarked however that still greater differences are indicated by Sonnerat in his figure and description of the Secretary of the Philippine Islands, and which, as far as the former was aware, had not been noticed by more recent naturalists. Whether or not the Secretaries of these three localities, the Cape of Good Hope, the Gambia, and the Philippines, may eventually turn out to be really distinct, or only varieties of the same species, must, he further remarked, be left for future observation; but, as it would be at least useful to direct the attention of travellers, collectors, and zoologists to the subject, he stated the principal marks which appeared to distinguish each, giving them provisionally specific names derived from the localities which they respectively inhabit as follows:—

1. *G. Capensis*, with the plume of long cervical feathers commencing upon the occiput, spreading irregularly over the upper part of the neck, narrow throughout the greater part of their length, as if the beard had been cut on each side close into the shaft of the quill, and spreading only at the point. Inhabits the Cape of Good Hope.

2. *G. Gambiensis*, with the cervical crest commencing some distance below the occiput, arranged in two regular series, one on each side of the neck, with the intermediate space clear, and composed of long spatule-shaped feathers, much broader throughout than in the last species, though similarly decreasing in width towards the root. In both these species the two middle feathers of the tail are considerably longer than the others. Inhabits Senegambia.

3. *G. Philippensis*, with the cervical crest spread irregularly from the occiput to the bottom of the neck, the longest feathers being those situated the lowest, which is just the reverse of what is observed in *G. Gambiensis*, and with the two exterior tail-feathers the longest, so that the tail appears forked. This is apparent not only in Sonnerat's

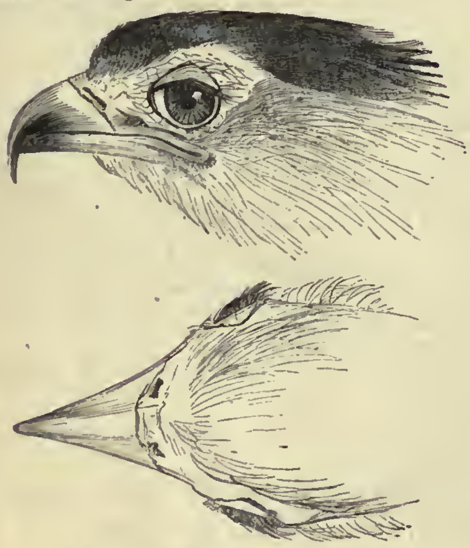
figure, but is expressly mentioned in his detailed description, and, if confirmed by future observation, is clearly indicative of a specific distinction. Inhabits the Philippine Islands. Described and figured in Sonnerat's 'Voyage à la Nouvelle Guinée,' p. 87, t. 50.

The colours of the three species or varieties here indicated do not, says Mr. Ogilby in conclusion, seem to be materially different in other respects.

Sonnerat commences his description by saying that the Secretary is not only found in the Philippines, but that it also inhabits Africa, and is known at the Cape of Good Hope. He speaks of the bird as being of the size of a turkey (Coq d'Inde), and as having the bill and feet of the Gallinaceous Birds, but notices that the legs are denuded of feathers to just above the knee. Of the accuracy of the description, as far as the alleged gallinaceous bill and feet are concerned, the student will have an opportunity of judging from the African specimens in our museums, and the living bird in the menagerie of the Zoological Society of London at the Regent's Park. But travellers and collectors will do well to bear Mr. Ogilby's provisional distinctions in mind; for the form, as we have seen, is so interesting to zoologists, that every modification of it must be considered of value. Speaking of the manners of the bird described in the 'Voyage à la Nouvelle Guinée,' Sonnerat says that it is sociable, and lives in a state of domesticity; that it hunts rats, and might, in this point of view, become useful in the colonies, where probably it would not be difficult to multiply it. Although he describes the bill and feet of the Secretary as being those of the Gallinaceous Birds, he states that it feeds on flesh, and ought consequently to be placed in the ranks of the Birds of Prey, among which, he adds, it forms an entirely insulated genus.

Gypogeranus is, as M. Lesson has stated, and as appears by its skeleton, a true Bird of Prey, with long legs: the number of the cervical vertebræ, an important feature according to the views of some zoologists, is thirteen, the atlas included. It is difficult to draw the line between the dorsal and cervical vertebræ in birds; but in two skeletons of the Secretary in the museum of the Royal College of Surgeons (No. 1207 and No. 1207*a*), there are nineteen vertebræ, counting from the ilium to the cranium, and of these thirteen may be considered cervical, because in them the costal processes are anchylosed.

The following are the generic characters of this bird:—Bill rather slender, shorter than the head, strong, very much hooked, curved nearly from its origin, and furnished with a cere at its base, rather vaulted, compressed at the point; nostrils placed at a small distance from the base, lateral, pierced in the cere, diagonal, oblong, open. Feet very long, slender, the tibia feathered, but not quite to what is called (improperly) the knee behind, whilst the feathers come a very little below the joint before; tarsus long, more slender below than in its upper part; toes short, warty below, the anterior toes united at the base by a membrane; hind toe articulated upon the tarsus. Wings long, armed with obtuse spurs; the first five quills the longest and nearly equal.



Bill of Secretary (*Gypogeranus Serpentarius*).

M. Lesson says that a single species (African) (*Falco Serpentarius*, Gmel.) composes this genus, and that attempts have been made to introduce the breed into the French sugar islands (Martinique, &c.), in the hope that it might diminish the race of the formidable *Trigonocephalus*, the Yellow Serpent of the Antilles (*Trigonocephalus lanceolatus*, Opp.), the most dangerous reptile of those parts, six or seven feet in length, and rivalling the Rattlesnake in the intensity of its poison.

Size, about three feet in length. Eye full, surrounded by a naked skin, with a series of hairs beneath the overshadowing feathers in the form of an eyebrow; eyelashes long and strong. Plumage, when perfect, for the most part bluish-gray, with a reddish-brown tinge on the wings; greater quills black. Throat and breast nearly white; rest of the under surface black, reddish, and white intermingled, the plumage of the legs bright black, with a slight intermixture of brownish rays. Occipital crest, which can be raised or depressed at pleasure, consisting of feathers without barbs at the base, but spreading out as they advance, and coloured of a mixed black and gray. Two middle tail-feathers longest.

Secretary (*Gypogeranus Serpentarius*).

The Secretaries live in pairs, and do not collect in flocks; they build on high trees; but if these are not to be had, in very close thickets. They run with considerable swiftness, and are approached with difficulty by the sportsman.

At first sight this bird resembles the Çariama (*Palamadea cristata*), but this is only an external resemblance, as their internal structure and habits differ much. [ÇARIAMA.] Both these birds are now to be seen alive in the Gardens of the Zoological Society, Regent's Park.

GYPS. [VULTURIDÆ.]

GYPSOCALLIS (Don), a genus of Plants belonging to the natural order *Ericaceæ*. It is one of the names proposed by David Don for a section of the genus *Erica*. These genera have not been generally adopted. (Don, *Dichlamydeous Plants*.)

GYPSUM, a native Sulphate of Lime. It is called also in various forms *Selenite*, *Plaster of Paris*, and *Alabaster*. It is monoclinate, and crystallises usually in right rhomboidal prisms with beveled sides. It has a hardness of 1·5 to 2·0. Its specific gravity is 2·31 to 2·33. The crystals are remarkably foliate in one direction and cleaving easily, affording laminæ that are flexible but not elastic. It occurs also in laminated masses often of large size. It is found also in fibrous masses with a satin lustre, in stellated or radiating forms consisting of narrow laminæ, and also granular and compact. When pure and crystallised it is quite clear and pellucid like glass, and has a pearly lustre. It is sometimes gray, yellow, reddish, brownish, and even black and opaque. It is composed of one atom of sulphuric acid and one atom of lime. In its crystallised form it is combined with water, thus:—

Sulphuric Acid	. 46·3	
Lime	. 32·9	
Water	. 20·8	
		100·0

Its formula is $SO_3 + CaO$. Before the blow-pipe it becomes instantly white and opaque, and exfoliates, and then falls to powder or crumbles easily in the fingers. It fuses with difficulty, and presents no action with acids.

The following are its principal varieties:—

Selenite, transparent and foliated.
Radiated Gypsum, having a radiated structure.
Satin Spar, or *Fibrous Gypsum*, with white and delicate fibres.
Alabaster, or *Snowy Gypsum*, white or light, with a very fine grain.
Plaster of Paris, when burnt and ground.

Gypsum in all its varieties, is readily distinguished from all other minerals, by its softness, by its becoming an opaque powder without fusing before the blow-pipe, and the absence of all effervescence or gelatinising with acids.

Sulphate of Lime is a frequent constituent of the strata of the earth. It is found in layers in the Magnesian Limestone, is abundant in the London Clay, and is a prominent constituent of many tertiary deposits, as that of Paris. It is constantly present in the river and spring waters of Great Britain. It is found in the Thames, in the springs of Bath and Bristol, and in many others. Gypsum is worked at Paris, ground and burned, hence called Plaster of Paris. When water is added to this powder it becomes a paste, which subsequently hardens; hence its varied uses in the arts, whenever the object is to procure casts or models in relief. Alabaster comes mostly from Castelino in Italy. It is cut into vases, statues, and ornaments of various kinds. Alabaster is also found in the Mammoth cave in Kentucky, United States. It occurs in singularly beautiful imitation of flowers, leaves, shrubberies, and vines. Massive Gypsum occurs abundantly in New York, accompanying the rocks which afford the brine springs. It is also found in Ohio, Illinois, Virginia, Tennessee, Arkansas, and Nova Scotia. It is abundant in many parts of Europe.

An anhydrous sulphate of lime is found, which is called *Anhydrite*. [ANHYDRITE.]

Gypsum is used as a manure. [MANURES, in ARTS AND SC. DIV.]

GYPSY-WORT. [LYCOPUS.]

GYRACA'NTHUS, a genus of Fossil Placoid Fishes, from the Mountain Limestone and Coal Strata. There are four British species.

GYR-FALCON. [FALCONIDÆ.]

GYRINIDÆ, a family of Coleopterous Insects belonging to the section *Pentamera*, and the sub-section *Hydrodephaga*, or Water-Beetles, and distinguished by the minute size of the antennæ, which are clubbed and shorter than the head, the second joint being dilated into a kind of ear externally; the two fore legs are long and advanced in front like arms, but the four posterior legs are very short and compressed, but broad, forming two pair of short strong oars. The eyes are four in number, two being placed above and two below; the palpi are very small; the thorax short and transverse; and the elytra oval, depressed, and obtuse at the extremity, leaving the tip of the abdomen exposed.

This family corresponds with the genus *Gyrinus* of Linnæus, and unlike the *Dyticidæ* to which they are nearly allied, these insects are distinguished by the metallic brilliancy of their covering; living for the most part on the surface of the water, they receive the impressions of the light in a more direct manner than the *Dyticidæ*, and are accordingly ornamented with tints of a brassy or bronzed metallic hue, which glitter in the sun in the greatest degree. The velocity with which they execute their evolutions upon the surface of the water is really surprising, and has obtained for them the name of Tourniquets by the French, and Whirligigs and Waterflies by the English. Sometimes indeed they remain stationary for a time, so that it seems easy to secure them, but on the least motion they are instantly alert, escaping with surprising agility and diving to the bottom of the water. The situation of their eyes adds greatly to their defence, enabling them to see objects both above and below them. In the 'Journal of a Naturalist' we find the following account of their proceedings:—"Water quiet, still water affords a place of action to a very amusing little fellow (*Gyrinus natator*), which about the month of April, if the weather be tolerably mild, we see gamboling upon the surface of the sheltered pool; and every schoolboy who has angled for minnows in the brook is well acquainted with this merry little swimmer in his shining black jacket. Retiring in the autumn, and reposing all the winter in the mud at the bottom of the pond, it awakens in the spring, rises to the surface, and commences its summer sports. They associate in small parties of ten or a dozen near the bank, where some little projection forms a bay or renders the water perfectly tranquil; and here they will circle round each other without contention, each in his sphere, and with no apparent object from morning until night with great sprightliness and animation, and so lightly do they move on the fluid, as to form only some faint and transient circles on its surface. Very fond of society; we seldom see them alone, or if parted by accident they soon rejoin their busy companions. One pool commonly affords space for the amusement of several parties, yet they do not unite or contend, but perform their cheerful circlings in separate family associations. If we interfere with their merriment they seem greatly alarmed, disperse or dive to the bottom, where their fears shortly subside, as we soon again see our merry little friends gamboling as before. When they dive to the bottom of the water in the manner above described, they carry with them a little bubble of air affixed to the extremity of their bodies. Also they are sometimes to be found flying, their well-formed wings permitting such an operation, while the high polish of the body protects them from the action of the water." With the exception of a few exotic species, the insects of this family are of a small size, seldom exceeding a quarter of an inch in length; and the largest ones do not reach one inch. Some of the species are found on the margins of the ocean. They emit when touched a disagreeable scent, arising from a milky fluid which exudes from the different parts of the body, and which is not readily dispelled. The structure of the fore legs indicates their mode of life, serving as arms to convey the food, which they find floating upon the surface of the water, and which consists of small dead insects, &c., to the mouth. The number of species of this family does not exceed 50 or 60, and of these not more than eight or nine are found in this country; of these the *Gyrinus natator* is the most common. It is of a brilliant bronzy black colour, with the sides of the body and antennæ metallic; the margins of the elytra and legs reddish. The elytra are ornamented with lines of impressed spots. About a quarter of an inch in length.

GYRINUS. [GYRINIDÆ.]

GYROCARPUS, a genus of Plants containing few species, but these few are widely distributed—one being found in South America on the mountains of New Granada and Caracas, a second on those of the Coromandel coast, and two others in the tropical parts of Australia. *Gyrocarpus* has, in conformity to the opinion of Mr. Brown, been considered as allied to and by some it has been placed in *Lauraceæ*. Blume refers it to his new order of *Illigereæ*. Dr. Lindley considers it as belonging to *Combretaceæ*. The flowers are polygamous or hermaphrodite; the perianth superior, 4- to 8-fid; stamens 4, opposite to divisions of perianth; anthers 2-celled, with the cells opening by a valve from below upwards; drupe 1-seeded, having attached to it two long membranous wings, the prolongation of two divisions of the perianth as in *Dipterocarpeæ*. The embryo is inverse; the cotyledons twisted spirally. The American is so closely allied to the Asiatic species as to have been thought identical by Dr. Roxburgh. The latter grows to be a large tree with cordate leaves, which are deciduous about the end of the rainy season; after which the flowers make their appearance in the cold weather, but are shortly followed by the new leaves. The wood of this tree is whitish-coloured and very light. It is preferred whenever procurable for making the catamarans, or rafts, on which the natives come off to ships through the heavy surf of the Madras coast.

GY'RODUS (γῦρος, round, ὀδούς, a tooth), a genus of Fossil Fishes established by Agassiz. The mouth of these fishes was armed with rows of round grinding teeth in the palate for the crushing of hard *Crustacea* and fishes with bony scales. In very fine specimens five rows, which were placed on the os vomer in the roof of the mouth, remain in the stone, though no other part of the head is preserved; but generally the teeth are loose, and were in that state termed *Bufonites* by the old writers (Llwyd, &c.) on organic remains. (Buckland's 'Bridgewater Treatise.') The fishes of this genus belong to the Oolitic Strata.

GYROGONITES (γῦρος, round, γωνία, angle). This name was given by Lamarck to small fossil bodies found in fresh-water tertiary strata (Isle of Wight, near Paris, &c.), under the supposition that they were shells of Polythalamous *Cephalopoda*. ('Animaux sans Vertèbres,' tom. vii.) Lamarck was aware that his opinion was contested, and that some persons imagined the small globular transversely carinated *Gyrogonites* were the seeds of an aquatic plant, but he "could not believe it." It was however demonstrated in the 'Geological Transactions' (vol. ii., second series), that they were in truth the fruits of *Chara*, a genus of plants found in many fresh-water ponds. The stem and other parts of this plant are very calcareous. (Brongniart, *Histoire des Végétaux Fossiles*, article 'Characeæ;' Lyell, 'Memoir,' in *Geological Transactions*, vol. ii., new series.)

GYRO'LEPIS, a genus of Fossil Ganoid Fishes, from the New Red-Sandstone Strata and bone-beds of the Lias. There are three British species. (Agassiz.)

GYRO'NCHUS, a genus of Fossil Ganoid Fishes, from the Oolite of Stonesfield. (Agassiz.)

GYROPHORA. [LICHENS.]

GYROPRI'STIS, a genus of Fossil Placoid Fishes, from the Red-Sandstone near Belfast. (Agassiz.)

GYRO'STEUS, a genus of Fossil Ganoid Fishes, from the Lias. (Agassiz.)
